# Comparative analyses of expected shortfall and value-at-risk under market stress ${ }^{1}$ 

Yasuhiro Yamai and Toshinao Yoshiba, Bank of Japan

#### Abstract

In this paper, we compare value-at-risk (VaR) and expected shortfall under market stress. Assuming that the multivariate extreme value distribution represents asset returns under market stress, we simulate asset returns with this distribution. With these simulated asset returns, we examine whether market stress affects the properties of VaR and expected shortfall. Our findings are as follows. First, VaR and expected shortfall may underestimate the risk of securities with fat-tailed properties and a high potential for large losses. Second, VaR and expected shortfall may both disregard the tail dependence of asset returns. Third, expected shortfall has less of a problem in disregarding the fat tails and the tail dependence than VaR does.

## 1. Introduction

It is a well known fact that value-at-risk ${ }^{2}$ (VaR) models do not work under market stress. VaR models are usually based on normal asset returns and do not work under extreme price fluctuations. The case in point is the financial market crisis of autumn 1998. Concerning this crisis, CGFS (1999) notes that "a large majority of interviewees admitted that last autumn's events were in the "tails" of distributions and that VaR models were useless for measuring and monitoring market risk". Our question is this: Is this a problem of the estimation methods, or of VaR as a risk measure?
The estimation methods used for standard VaR models have problems for measuring extreme price movements. They assume that the asset returns follow a normal distribution. So they disregard the fat-tailed properties of actual returns, and underestimate the likelihood of extreme price movements.
On the other hand, the concept of VaR as a risk measure has problems for measuring extreme price movements. By definition, VaR only measures the distribution quantile, and disregards extreme loss beyond the VaR level. Thus, VaR may ignore important information regarding the tails of the underlying distributions. CGFS (2000) identifies this problem as tail risk.
To alleviate the problems inherent in VaR, Artzner et al $(1997,1999)$ propose the use of expected shortfall. Expected shortfall is the conditional expectation of loss given that the loss is beyond the VaR level. ${ }^{3}$ Thus, by definition, expected shortfall considers loss beyond the VaR level. Yamai and Yoshiba (2002c) show that expected shortfall has no tail risk under more lenient conditions than VaR.

[^0]$$
E S_{\alpha}(Z)=E\left[Z \mid Z \geq \operatorname{Va} R_{\alpha}(Z)\right]
$$

The existing research implies that the tail risk of VaR and expected shortfall may be more significant under market stress than under normal market conditions. The loss under market stress is larger and less frequent than that under normal conditions. According to Yamai and Yoshiba (2002a), the tail risk is significant when asset losses are infrequent and large. ${ }^{4}$

In this paper, we examine whether the tail risk of VaR and expected shortfall is actually significant under market stress. We assume that the multivariate extreme value distributions represent the asset returns under market stress. With this assumption, we simulate asset returns with those distributions, and compare VaR and expected shortfall. ${ }^{5,6}$

Our assumption of the multivariate extreme value distributions is based on the theoretical results of extreme value theory. This theory states that the multivariate exceedances over a high threshold asymptotically follow the multivariate extreme value distributions. As extremely large fluctuations characterise asset returns under market stress, we assume that the asset returns under market stress follow the multivariate extreme value distributions.

Following this Introduction, Section 2 introduces the concepts and definitions of the tail risk of VaR and expected shortfall based on Yamai and Yoshiba (2002a, 2002c). Section 3 provides a general introduction to multivariate extreme value theory. Section 4 adopts univariate extreme value distributions to examine how the fat-tailed properties of these distributions result in the problems of VaR and expected shortfall. Section 5 adopts simulations with multivariate extreme value distributions ${ }^{7}$ to examine how tail dependence results in the tail risk of VaR and expected shortfall. Section 6 presents empirical analyses to examine whether past financial crisis have resulted in the tail risk of VaR and expected shortfall. Finally, Section 7 presents the conclusions and implications of this paper.

## 2. Tail risk of VaR and expected shortfall

## A. The definition and concept of the tail risk of VaR

In this paper, we say that $\operatorname{VaR}$ has tail risk when $\operatorname{VaR}$ fails to summarise the relative choice between portfolios as a result of its underestimation of the risk of portfolios with fat-tailed properties and a high potential for large losses. ${ }^{8,9}$ The tail risk of VaR emerges since it measures only a single quantile of the profit/loss distributions and disregards any loss beyond the VaR level. This may lead one to think that securities with a higher potential for large losses are less risky than securities with a lower potential for large losses.

For example, suppose that the VaR at the $99 \%$ confidence level of portfolio A is 10 million and that of portfolio $B$ is 15 million. Given these numbers, one may conclude that portfolio $B$ is more risky than portfolio $A$. However, the investor does not know how much may be lost outside of the confidence

[^1]interval. When the maximum loss of portfolio $A$ is 1 trillion and that of $B$ is 16 million, portfolio $A$ should be considered more risky since it loses much more than portfolio B under the worst case. In this case, $\operatorname{VaR}$ has tail risk since VaR fails to summarise the choice between portfolios $A$ and $B$ as a result of its disregard of the tail of profit/loss distributions.

We further illustrate the concept of the tail risk of VaR with two examples.

## Example 1: Option portfolio (Danielsson (2001))

Danielsson (2001) shows that VaR is conducive to manipulation since it measures only a single quantile. We introduce his illustration as a typical example of the tail risk of VaR.
The solid line in Figure 1 depicts the distribution function of the profit/loss of a given security. The VaR of this security is $\mathrm{VaR}_{0}$ as it is the lower quantile of the profit/loss distribution.

One is able to decrease this VaR to an arbitrary level by selling and buying options of this security. Suppose the desired VaR level is $\mathrm{VaR}_{D}$. One way to achieve this is to write a put with a strike price right below $\mathrm{VaR}_{0}$ and buy a put with a strike price just above $\mathrm{VaR}_{D}$. The dotted line in Figure 1 depicts the distribution function of the profit/loss after buying and selling the options. The VaR is decreased from $\mathrm{VaR}_{0}$ to $\mathrm{VaR}_{D}$. This trading strategy increases the potential for large loss. The right end of Figure 1 shows that the probability of large loss is increased.

This example shows that the tail risk of VaR can be significant with simple option trading. One is able to manipulate VaR by buying and selling options. As a result of this manipulation, the potential for large loss is increased. VaR fails to consider this perverse effect since it disregards any loss beyond the confidence level.

## Example 2: Credit portfolio (Lucas et al (2001))

The next example demonstrates the tail risk of VaR in a credit portfolio, using the result of Lucas et al (2001).

Lucas et al (2001) derive an analytic approximation to the credit loss distribution of large portfolios. To illustrate their general result, they provide a simple example of credit loss calculation. ${ }^{10}$ They consider a bond portfolio where the amount of credit exposure for individual bonds is identical and the default is triggered by a single factor. For simplicity, they assume that the loss is recognised in the default mode and that the factor sensitivities of the latent variables and default probabilities are homogeneous. ${ }^{11}$ They show that the credit loss of the bond portfolio converges almost surely to $C$, as defined in the following equation, when the number of bonds approaches infinity (Lucas et al (2001, p 1643, equation (14)).

$$
\begin{equation*}
C \approx \Phi\left(\frac{s-\rho Y}{\sqrt{1-\rho^{2}}}\right) \tag{1}
\end{equation*}
$$

$\Phi \quad$ :The distribution function of the standard normal distribution
$Y \quad:$ Random variable following the standard normal distribution
$s \quad$ The value of $\Phi^{-1}(p)$ when the default rate is $p$, and $\Phi^{-1}$ is the inverse of $\Phi$.
$\rho \quad$ :Correlation coefficient among the latent variables
Based on this result, we calculate the distribution functions of the limiting credit loss $C$ for $\rho=0.7$ and 0.9, and plot them in Figure 2.

The results show that VaR has tail risk. The bond portfolio is more concentrated when $\rho=0.9$ than when $\rho=0.7$. The tail of the credit loss distribution is fatter when $\rho=0.9$ than when $\rho=0.7$. Thus, the

[^2]bond portfolio is more risky when $\rho=0.9$ than when $\rho=0.7$. However, the VaR at the $95 \%$ confidence interval is higher when $\rho=0.7$ than when $\rho=0.9$. This shows that VaR fails to consider credit concentration since it disregards the loss beyond the confidence level.

The preceding examples show that VaR has tail risk when the loss distributions intersect beyond the confidence level. In such cases, one is able to decrease VaR by manipulating the tails of the loss distributions. This manipulation of the distribution tails increases the potential for extreme losses, and may lead to a failure of risk management. This problem is significant when the portfolio profit/loss is non-linear and the distribution function of the profit/loss is discontinuous. ${ }^{12}$

## B. The tail risk of expected shortfall

We define the tail risk of expected shortfall in the same way as the tail risk of VaR. In this paper, we say that expected shortfall has tail risk when expected shortfall fails to summarise the relative choice between portfolios as a result of its underestimation of the risk of portfolios with fat-tailed properties and a high potential for large losses.

To illustrate our definition of the tail risk of expected shortfall, we present an example from Yamai and Yoshiba (2002c). Table 1 shows the payoff and profit/loss of two sample portfolios A and B. The expected payoff and the initial investment amount of both portfolios are equal at 97.05.
In most of the cases, both portfolios A and B do not incur large losses. The probability that the loss is less than 10 is about $99 \%$ for both portfolios.
The magnitude of extreme loss is different. Portfolio A never loses more than half of its value while Portfolio B may lose three quarters of its value. Thus, portfolio B is more risky than Portfolio A when one is worried about extreme loss.

Table 2 shows the VaR and expected shortfall of the two portfolios at the $99 \%$ confidence level. Both VaR and expected shortfall are higher for Portfolio A, which has a lower magnitude of extreme loss. Thus, expected shortfall has tail risk since it chooses the more risky portfolio as a result of its disregard of extreme losses.
The example above shows that expected shortfall may have tail risk. However, the tail risk of expected shortfall is less significant than that of VaR. Yamai and Yoshiba (2002c) show that expected shortfall has no tail risk under more lenient conditions than VaR. This is because VaR completely disregards any loss beyond the confidence level while expected shortfall takes this into account as a conditional expectation.

## 3. Multivariate extreme value theory

In this section, we give a brief introduction to multivariate extreme value theory. ${ }^{13}$ We use this theory to represent asset returns under market stress in the following sections.

Multivariate extreme value theory consists of two modelling aspects: the tails of the marginal distributions and the dependence structure among extreme values.
We restrict our attention to the bivariate case in this paper.

[^3]
## A. Univariate extreme value theory

Let $Z$ denote a random variable and $F$ the distribution function of $Z$. We consider extreme values in terms of exceedances with a threshold $\theta(\theta>0)$. The exceedances are defined as $m_{\theta}(Z)=\max (Z, \theta)$. $Z$ is larger than $\theta$ with probability $p$, and smaller than $\theta$ with probability $1-p$. Then, by the definition of exceedances, $p=1-F(\theta)$. We call $p$ tail probability.

The conditional distribution $F_{\theta}$ defined below gives the stochastic behaviour of extreme values.

$$
\begin{equation*}
F_{\theta}(x)=\operatorname{Pr}\{Z-\theta \leq x \mid Z>\theta\}=\frac{F(x)-F(\theta)}{1-F(\theta)}, \theta \leq x . \tag{2}
\end{equation*}
$$

This is the distribution function of $(Z-\theta)$ given that $Z$ exceeds $\theta . F_{\theta}$ is not known precisely unless $F$ is known.

The extreme value theory tells us the approximation to $F_{\theta}$ that is applicable for high values of threshold $\theta$. The Pickands-Balkema-de Haan theorem shows that as the value of $\theta$ tends to the right end point of $F, F_{\theta}$ converges to a generalised Pareto distribution. The generalised Pareto distribution is represented as follows: ${ }^{14,15}$

$$
\begin{equation*}
G_{\xi, \sigma}(x)=1-\left(1+\xi \cdot \frac{x}{\sigma}\right)^{-1 / \xi}, x \geq 0 . \tag{3}
\end{equation*}
$$

With equations (1) and (2), when the value of $\theta$ is sufficiently large, the distribution function of exceedances $m_{\theta}(Z)$, denoted by $F_{m}(x)$, is approximated as follows:

$$
\begin{equation*}
F_{m}(x) \approx(1-F(\theta)) G_{\xi, \sigma}(x-\theta)+F(\theta)=1-p\left(1+\xi \cdot \frac{x-\theta}{\sigma}\right)^{-1 / \xi}, x \geq \theta \tag{4}
\end{equation*}
$$

In this paper, we call $F_{m}(x)$ the distribution of exceedances.
The distribution of exceedances is described by three parameters: the tail index $\xi$, the scale parameter $\sigma$, and the tail probability $p$. The tail index $\xi$ represents how fat the tail of the distribution is, so the tail is fat when $\xi$ is large (see Figure 3). The scale parameter $\sigma$ represents how dispersed the distribution is, so the distribution is dispersed when $\sigma$ is large (see Figure 4). The tail probability $p$ determines the threshold $\theta$ as $F_{m}(\theta) \approx 1-p$.

When the confidence level of $\operatorname{VaR}$ and expected shortfall is less than $p$, the distribution of exceedances is used to calculate VaR and expected shortfall. (See Section 4 for the specific calculations.)

## B. Copula

As a preliminary to the dependence modelling of extreme values, we provide a simple explanation of copula. ${ }^{16}$
Suppose we have two-dimensional random variables $\left(Z_{1}, Z_{2}\right)$. Their joint distribution function $F\left(x_{1}, x_{2}\right)=P\left[Z_{1} \leq x_{1}, Z_{2} \leq x_{2}\right]$ fully describes their marginal behaviour and dependence structure. The main idea of copula is that we separate this joint distribution into the part that describes the dependence structure and the part that describes the marginal behaviour.
Let $\left(F_{1}\left(x_{1}\right), F_{2}\left(x_{2}\right)\right)$ denote the marginal distribution functions of $\left(Z_{1}, Z_{2}\right)$. Suppose we transform $\left(Z_{1}, Z_{2}\right)$ to have standard uniform marginal distributions. ${ }^{17}$ This is done by $\left(Z_{1}, Z_{2}\right) \mapsto\left(F_{1}\left(Z_{1}\right), F_{2}\left(Z_{2}\right)\right)$. The joint

[^4]distribution function $C$ of the random variable $\left(F_{1}\left(Z_{1}\right), F_{2}\left(Z_{2}\right)\right)$ is called the copula of the random vector $\left(Z_{1}, Z_{2}\right)$. It follows that:
$F\left(x_{1}, x_{2}\right)=P\left[Z_{1} \leq x_{1}, Z_{2} \leq x_{2}\right]=C\left(F_{1}\left(x_{1}\right), F_{2}\left(x_{2}\right)\right)$.
Sklar's theorem shows that (4) holds with any $F$ for some copula $C$ and that $C$ is unique when $F_{1}\left(x_{1}\right)$ and $F_{2}\left(x_{2}\right)$ are continuous.

In general, the copula is defined as the distribution function of a random vector with standard uniform marginal distributions. In other words, the distribution function $C$ is a copula function for the two random variables $U_{1}, U_{2}$ that follow the standard uniform distribution.

$$
\begin{equation*}
C\left(u_{1}, u_{2}\right)=\operatorname{Pr}\left[U_{1} \leq u_{1}, U_{2} \leq u_{2}\right] . \tag{6}
\end{equation*}
$$

One of the most important properties of the copula is its invariance property. This property says that a copula is invariant under increasing and continuous transformations of the marginals. That is, when the copula of $\left(Z_{1}, Z_{2}\right)$ is $C\left(u_{1}, u_{2}\right)$ and $h_{1}(\bullet), h_{2}(\bullet)$ are increasing continuous functions, the copula of $\left(h_{1}\left(Z_{1}\right), h_{2}\left(Z_{2}\right)\right)$ is also $C\left(u_{1}, u_{2}\right)$.
The invariance property and Sklar's theorem show that a copula is interpreted as the dependence structure of random variables. The copula represents the part that is not described by the marginals, and is invariant under the transformation of the marginals.

## C. Multivariate extreme value theory

We give a brief illustration of the bivariate exceedances approach as a model for the dependence structure of extreme values. ${ }^{18}$

Let $Z=\left(Z_{1}, Z_{2}\right)$ denote the two-dimensional vector of random variables and $F\left(Z_{1}, Z_{2}\right)$ the distribution function of $Z$. The bivariate exceedances of $Z$ correspond to the vector of univariate exceedances defined with a two-dimensional vector of threshold $\theta=\left(\theta_{1}, \theta_{2}\right)$ (see Figure 5). These exceedances are defined as follows:

$$
\begin{equation*}
m_{\left(\theta_{1}, \theta_{2}\right)}\left(Z_{1}, Z_{2}\right)=\left(\max \left(Z_{1}, \theta_{1}\right), \max \left(Z_{2}, \theta_{2}\right)\right) \tag{7}
\end{equation*}
$$

The marginal distributions of the bivariate exceedances defined in (6) converge to the distribution of exceedances introduced in Section 3.A when the thresholds tend to the right end points of the marginal distributions. This is because the bivariate exceedance is the vector of univariate exceedances whose distribution converges to a generalised Pareto distribution.
The copula of bivariate exceedances also converges to a class of copula that satisfies several conditions. Ledford and Tawn (1996) show that this class is represented by the following equation (see Appendix A for details):

$$
\begin{equation*}
C\left(u_{1}, u_{2}\right)=\exp \left\{-V\left(-\frac{1}{\log u_{1}},-\frac{1}{\log u_{2}}\right)\right\}, \tag{8}
\end{equation*}
$$

where

$$
\begin{equation*}
V\left(z_{1}, z_{2}\right)=\int_{0}^{1} \max \left\{s z_{1}^{-1},(1-s) z_{2}^{-1}\right\} d H(s) \tag{9}
\end{equation*}
$$

and $H$ is a non-negative measure on $[0,1]$ satisfying the following condition:

$$
\begin{equation*}
\int_{0}^{1} s d H(s)=\int_{0}^{1}(1-s) d H(s)=1 \tag{10}
\end{equation*}
$$

Following Hefferman (2000), we call this type of copula the bivariate extreme value copula or the extreme value copula.

[^5]The class of the extreme value copula is wide, being constrained only by (9). We have an infinite number of parameterised extreme value copulas. In practice, we choose a parametric family of copula that satisfies (9), and use the copula for the analysis of bivariate extreme values.

One standard type of bivariate extreme value copula is the Gumbel copula. The Gumbel copula is the most frequently used extreme value copula for applied statistics, engineering and finance (Gumbel (1960), Tawn (1988), Embrechts et al (2002), McNeil (2000), Longin and Solnik (2001)). The Gumbel copula is expressed by:

$$
\begin{equation*}
C\left(u_{1}, u_{2}\right)=\exp \left\{-\left[\left(-\log u_{1}\right)^{\alpha}+\left(-\log u_{2}\right)^{\alpha}\right]^{1 / \alpha}\right\}, \tag{11}
\end{equation*}
$$

for a parameter $\alpha \in[1, \infty]$. We obtain (10) by defining $V$ in (8) as follows:

$$
\begin{equation*}
V\left(z_{1}, z_{2}\right)=\left(z_{1}^{-\alpha}+z_{2}^{-\alpha}\right)^{1 / \alpha} . \tag{12}
\end{equation*}
$$

The dependence parameter $\alpha$ controls the level of dependence between random variables. $\alpha=1$ corresponds to full dependence and $\alpha=\infty$ corresponds to independence.
The Gumbel copula has several advantages over other parameterised extreme value copulas. ${ }^{19}$ It includes the special cases of independence and full dependence, and only one parameter is needed to model the dependence structure. The Gumbel copula is tractable, which facilitates simulations and maximum likelihood estimations. Given these advantages, we adopt the Gumbel copula as the extreme value copula.

To summarise, extreme value theory shows that the bivariate exceedances asymptotically follow a joint distribution whose marginals are the distributions of exceedances and whose copula is the extreme value copula.

## D. Tail dependence

We introduce the concept of tail dependence between random variables. Suppose that a random vector $\left(Z_{1}, Z_{2}\right)$ has a joint distribution function $F\left(Z_{1}, Z_{2}\right)$ with marginals $F_{1}\left(x_{1}\right), F_{2}\left(x_{2}\right)$.
Assume that marginals are equal. We define a dependence measure $\chi$ as follows:
$\chi \equiv \lim _{z \rightarrow z^{+}} \operatorname{Pr}\left\{Z_{1}>z \mid Z_{2}>z\right\}$,
where $z^{+}$is the right end point of $F$.
$\chi$ measures the asymptotic survival probability over one value to be large given that the other is also large. When $\chi=0$, we say $Z_{1}$ and $Z_{2}$ are asymptotically independent. When $\chi>0$, we say $Z_{1}$ and $Z_{2}$ are asymptotically dependent. $\chi$ increases with the strength of dependence within the class of asymptotically dependent variables.

When $F$ has different marginals $F_{Z_{1}}$ and $F_{Z_{2}}, \chi$ is defined as follows:
$\chi \equiv \lim _{u \rightarrow 1} \operatorname{Pr}\left\{F_{Z_{1}}\left(Z_{1}\right)>u \mid F_{Z_{2}}\left(Z_{2}\right)>u\right\}$.

Further defining the other dependence measure $\chi(u)$ as in (14), the relationship $\chi=\lim _{u \rightarrow 1} \chi(u)$ holds (Coles et al (1999)).
$\chi(u) \equiv 2-\frac{\log \operatorname{Pr}\left\{F_{Z_{1}}\left(Z_{1}\right)<u, F_{Z_{2}}\left(Z_{2}\right)<u\right\}}{\log \operatorname{Pr}\left\{F_{Z_{1}}\left(Z_{1}\right)<u\right\}}$, for $0 \leq u \leq 1$.

[^6]Although $\chi$ measures dependence when random variables are asymptotically dependent, it fails to do so when random variables are asymptotically independent. When random variables are asymptotically independent, $\chi=0$ by definition and $\chi$ is unable to provide dependence information.

The class of asymptotically independent copulas includes important copulas such as the Gaussian copula and the Frank copula, which are introduced in the next section. Ledford and Tawn $(1996,1997)$ and Coles et al (1999) say that the asymptotically independent case is important in the analysis of multivariate extreme values.

To counter this shortcoming of the dependence measure $\chi$, Coles et al (1999) propose a new dependence measure $\bar{\chi}$ as defined below.
$\bar{\chi} \equiv \lim _{u \rightarrow 1} \bar{\chi}(u)$
where $\bar{\chi}(u) \equiv \frac{2 \log \operatorname{Pr}\left\{F_{Z_{1}}\left(Z_{1}\right)>u\right\}}{\log \operatorname{Pr}\left\{F_{Z_{1}}\left(Z_{1}\right)>u, F_{Z_{2}}\left(Z_{2}\right)>u\right\}}-1$
$\bar{\chi}$ measures dependence within the class of asymptotically independent variables. For asymptotically independent random variables, $-1<\bar{\chi}<1$. For asymptotically dependent random variables, $\bar{\chi}=1$.

Thus, the combination $(\chi, \bar{\chi})$ measures tail dependence for both asymptotically dependent and independent case (see Table 3). For asymptotically dependent random variables, $\bar{\chi}=1$ and $\chi$ measures tail dependence. For asymptotically independent random variables, $\chi=0$ and $\bar{\chi}$ measures tail dependence.

## E. Copula and tail dependence

With some calculations, it is shown that $\chi(u)$ is constant for the bivariate extreme value copula as follows:
$\chi(u)=\chi=2-V(1,1)$. for all $0 \leq u \leq 1$.
For the Gumbel copula, this becomes $\chi=2-2^{1 / \alpha}(\alpha \geq 1)$ (see Table 4). Thus, for the bivariate extreme value copula, random variables are either independent or asymptotically dependent. In other words, the bivariate extreme copula is unable to represent the dependence structure when random variables are asymptotically independent.

Ledford and Tawn (1996, 1997) and Coles (2001) say that multivariate exceedances may be asymptotically independent and that modelling multivariate exceedances with the extreme value copula is likely to lead to misleading results in this case. They say that the use of asymptotically independent copulas is effective when the multivariate exceedances are asymptotically independent. Hefferman (2000) provides a list of asymptotically independent copulas that are useful for modelling multivariate extreme values.

In this paper, we adopt the Gaussian copula and the Frank copula as asymptotically independent copulas. These are defined as follows (see Table 4).

## Gaussian copula

$$
\begin{equation*}
C(u, v)=\Phi_{\rho}\left(\Phi^{-1}(u), \Phi^{-1}(v)\right) \tag{19}
\end{equation*}
$$

where $\Phi_{\rho}$ is the distribution function of a bivariate standard normal distribution with a correlation coefficient $\rho$, and $\Phi^{-1}$ is the inverse function of the distribution function for the univariate standard normal distribution.

## Frank copula ${ }^{20}$

$C(u, v)=-\frac{1}{\delta} 1 n\left(\frac{1-e^{-\delta}-\left(1-e^{-\delta u}\right)\left(1-e^{-\delta v}\right)}{1-e^{-\delta}}\right)$.
The dependence parameters $\rho$ and $\delta$ control the level of dependence between random variables. For the Gaussian copula, $\rho= \pm 1$ corresponds to full dependence and $\rho=0$ corresponds to independence.
For the Frank copula, $\delta= \pm \infty$ corresponds to full dependence and $\delta=0$ corresponds to independence.
For both of these copulas, random variables are asymptotically independent. For the Gaussian copula with $-1<\rho<1, \chi=0$ and $\bar{\chi}=\rho$. For the Frank copula, $\chi=\bar{\chi}=0 .{ }^{21}$ The latter shows that the Frank copula has very weak tail dependence.

The use of asymptotically independent copula for modelling multivariate exceedances may bring some doubt since extreme value theory shows that the asymptotic copula of exceedances is the extreme value copula. However, the rate of convergence of marginals may be higher than that of the copula. In this case, the generalised Pareto distribution well approximates the marginals of exceedances while the extreme value copula does not approximate the dependence structure of exceedances. Thus, in some cases, it is valid to assume that marginals are modelled by the generalised Pareto distribution while dependence is modelled by asymptotically independent copula.

## 4. The tail risk under univariate extreme value distribution

In this section, we examine whether VaR and expected shortfall have tail risk when asset returns are described by the univariate extreme value distribution. We use (4) to calculate the VaR and expected shortfall of two securities with different tail fatness, and examine whether VaR and expected shortfall underestimate the risk of securities with fat-tailed properties and a high potential for large loss.
Suppose $Z_{1}$ and $Z_{2}$ are random variables denoting the loss of two securities. Using the univariate extreme value theory introduced in Section 3.A, with high thresholds, the exceedances of $Z_{1}$ and $Z_{2}$ follow the distributions below:

$$
\begin{align*}
& F_{m\left(z_{1}\right)}(x)=1-p_{1}\left(1+\xi_{1} \cdot \frac{x-\theta_{1}}{\sigma_{1}}\right)^{-1 / \xi_{1}},  \tag{21}\\
& F_{m\left(z_{2}\right)}(x)=1-p_{2}\left(1+\xi_{2} \cdot \frac{x-\theta_{2}}{\sigma_{2}}\right)^{-1 / \xi_{2}} . \tag{22}
\end{align*}
$$

As an example of the tail risk of $\operatorname{VaR}$, we set the parameter values as follows: the tail probability is $p_{1}=p_{2}=0.1$; the threshold value is $\theta_{1}=\theta_{2}=0.05$; the tail indices are $\xi_{1}=0.1$ and $\xi_{2}=0.5$; and the scale parameters are $\sigma_{1}=0.05$ and $\sigma_{2}=0.035$. Figure 6 plots (21) and (22) with this parameter setting.

Figure 6 shows that $\operatorname{VaR}$ has tail risk in this example. Given $\xi_{2}>\xi_{1}, Z_{2}$ has a fatter tail than $Z_{1}$ (see Section 3.A). Thus, $Z_{2}$ has a higher potential for large loss than $Z_{1}$. However, Figure 6 shows that the VaR at the $95 \%$ confidence level is higher for $Z_{1}$ than for $Z_{2}$. Thus, VaR indicates that $Z_{1}$ is more risky than $Z_{2}$. As in the two examples in Section 2.A, VaR has tail risk as the distribution functions intersect beyond the VaR confidence level.

[^7]We derive the conditions for the tail risk of VaR. Following McNeil (2000), we calculate the VaR from (21) and (22). Let $\operatorname{VaR}_{a}(Z)$ denote the $\operatorname{VaR}$ of $Z$ at the $(1-\alpha)$ confidence level. Since VaR is the upper $(1-\alpha)$ quantile of the loss distribution, the following holds:
$1-\alpha \approx 1-p\left(1+\xi \cdot \frac{V_{a} R_{\alpha}(Z)-\theta}{\sigma}\right)^{-1 / 5}$.
We then solve (23) to obtain the following:
$\operatorname{VaR}_{\alpha}(Z) \approx \theta+\frac{\sigma}{\xi}\left(\left(\frac{p}{\alpha}\right)^{\xi}-1\right)$.
With (24), we derive the condition of the tail risk of VaR as follows. Without the loss of generality, we assume $\xi_{2}>\xi_{1}$, or that the tail of $Z_{2}$ is fatter than the tail of $Z_{1}$. In other words, $Z_{2}$ has higher potential for extreme loss than $Z_{1}$. VaR has tail risk when the $\operatorname{VaR}$ of $Z_{2}$ is smaller than that of $Z_{1}$, or when the following inequality holds:
$\operatorname{VaR}_{\alpha}\left(Z_{1}\right)>\operatorname{Va} R_{\alpha}\left(Z_{2}\right)$.
Assuming $\theta_{1}=\theta_{2}$ and $p_{1}=p_{2}=p$ for simplification, we obtain the following condition from (24) and (25):
$\frac{\sigma_{1}}{\sigma_{2}}>\bar{\kappa}_{V a R}$, where $\bar{\kappa}_{V a R}=\frac{\xi_{1}}{\xi_{2}}\left(\frac{(p / \alpha)^{\xi_{2}}-1}{(p / \alpha)^{\xi_{1}}-1}\right)$.
The value $\bar{\kappa}_{V a R}$ indicates how strict the condition for the tail risk of VaR is. When $\bar{\kappa}_{V a R}$ is small, a small difference between the scale parameters $\sigma_{1}$ and $\sigma_{2}$ brings about tail risk of VaR. When $\bar{\kappa}_{\text {VaR }}$ is large, a large difference between $\sigma_{1}$ and $\sigma_{2}$ is needed to bring about tail risk of VaR .

Table 5 shows the value of $\bar{\kappa}_{V a R}$ with varying $\left(\xi_{1}, \xi_{2}\right)$ for VaR at the $95 \%$ and $99 \%$ confidence levels, when $p$ is 0.05 and $0.1 .^{22}$ This table shows two aspects of this condition.

First, the scale parameter of the thin-tailed distribution $\sigma_{1}$ must be larger than the scale parameter of the fat-tailed distribution $\sigma_{2}$. This is because $\bar{\kappa}_{V a R}>1$ for all combinations of $\left(\xi_{1}, \xi_{2}\right)$.

Figure 7 illustrates this point. The figure plots the distribution of exceedance with parameter values $\xi_{1}=0.5, \sigma_{1}=1$. The figure also plots the distribution of exceedances with parameter values $\xi_{2}=0.1$ and $\sigma_{2}=1,1.5$ and 2. Here, we denote the $\operatorname{VaR}$ for $\xi_{1}=0.5, \sigma_{1}=1$ as $\operatorname{VaR}\left(\xi_{1}=0.5, \sigma_{1}=1\right)$ and that for $\xi_{2}=0.1, \sigma_{2}=\sigma$ as $\operatorname{VaR}\left(\xi_{2}=0.1, \sigma_{2}=\sigma\right)$. The distribution with $\xi_{1}=0.5$ has a fatter tail and higher potential for large loss than the distribution with $\xi_{2}=0.1$. Thus, VaR has tail risk if $\operatorname{VaR}\left(\xi_{1}=0.5, \sigma_{1}=1\right)<\operatorname{VaR}\left(\xi_{2}=0.1, \sigma_{2}=\sigma\right)$.

From the figure, we find $\operatorname{VaR}\left(\xi_{1}=0.5, \sigma_{1}=1\right)<\operatorname{VaR}\left(\xi_{2}=0.1, \sigma_{2}=2\right)$ with a confidence level below $99 \%$, and $\operatorname{VaR}\left(\xi_{1}=0.5, \sigma_{1}=1\right)<\operatorname{VaR}\left(\xi_{2}=0.1, \sigma_{2}=1.5\right)$ with a confidence level below $98 \%$. On the other hand, $\operatorname{VaR}\left(\xi_{1}=0.5, \sigma_{1}=1\right)>\operatorname{VaR}\left(\xi_{2}=0.1, \sigma_{2}=1\right)$ with a confidence level above $95 \%$. Therefore, VaR has tail risk with a high confidence level when the difference between the scale parameters is large.

Second, the smaller the difference between the tail indices $\xi_{1}$ and $\xi_{2}$, the more lenient the conditions for the tail risk of VaR. This is because $\bar{\kappa}_{V a R}$ is small when the difference between the tail indices is small.

Figure 8 illustrates this point. The figure plots the distribution of exceedances with parameter values $\xi_{1}=0.1, \sigma_{1}=1$. The figure also plots the distribution of exceedances with parameter values $\sigma_{2}=0.75$

[^8]and $\xi_{2}=0.3,0.5,0.9$. Here, we denote the $\operatorname{VaR}$ for $\xi_{1}=0.1, \sigma_{1}=1$ as $\operatorname{VaR}\left(\xi_{1}=0.1, \sigma_{1}=1\right)$ and that for $\xi_{2}=\xi, \sigma_{2}=0.75$ as $\operatorname{VaR}\left(\xi_{2}=\xi, \sigma_{2}=0.75\right)$. As the distribution tail is fatter with $\xi_{2}=\xi, \sigma_{2}=0.75$ than with $\xi_{1}=0.1, \sigma_{1}=1, \operatorname{VaR}$ has tail risk if $\operatorname{VaR}\left(\xi_{1}=0.1, \sigma_{1}=1\right)>\operatorname{VaR}\left(\xi_{2}=\xi, \sigma_{2}=0.75\right)$. We find $\operatorname{VaR}\left(\xi_{1}=0.1, \sigma_{1}=1\right)>\operatorname{VaR}\left(\xi_{2}=0.3, \sigma_{2}=0.75\right)$ with a confidence level below $99 \%$, and $\operatorname{VaR}\left(\xi_{1}=0.1, \sigma_{1}=1\right)>\operatorname{VaR}\left(\xi_{2}=0.5, \sigma_{2}=0.75\right)$ with a confidence level below $97 \%$. On the other hand, $\operatorname{VaR}\left(\xi_{1}=0.1, \sigma_{1}=1\right)<\operatorname{VaR}\left(\xi_{2}=0.9, \sigma_{2}=0.75\right)$ with a confidence level above $95 \%$. Therefore, $\operatorname{VaR}$ has tail risk with a high confidence level when the difference between the tail indices is small.
We analyse the condition for the tail risk of expected shortfall as we analysed that of VaR. Following McNeil (2000), we can calculate the expected shortfall of $Z$ at the $(1-\alpha)$ confidence level (denoted by $\left.E S_{a}(Z)\right)$ from (24). ${ }^{23}$
\[

$$
\begin{align*}
& E S_{\alpha}(Z)=E\left[Z \mid Z \geq \operatorname{VaR}_{\alpha}(Z)\right] \\
& \left.\quad=\operatorname{VaR}_{\alpha}(Z)+E[Z-\theta)-\left(\operatorname{VaR}_{\alpha}(Z)-\theta\right) \mid Z-\theta \geq \operatorname{VaR}_{\alpha}(Z)-\theta\right] \\
& \quad=\operatorname{VaR}_{\alpha}(Z)+\frac{\sigma+\xi \cdot\left(\operatorname{VaR}_{\alpha}(Z)-\theta\right)}{1-\xi}  \tag{27}\\
& \quad=\frac{\sigma-\xi \theta}{1-\xi}+\frac{\operatorname{VaR}_{\alpha}(Z)}{1-\xi} \approx \theta+\frac{\sigma}{1-\xi}\left\{1+\frac{1}{\xi}\left(\left(\frac{p}{\alpha}\right)^{\xi}-1\right)\right\} .
\end{align*}
$$
\]

Given $\xi_{2}>\xi_{1}$, expected shortfall has tail risk when the following inequality holds:

$$
\begin{equation*}
E S_{\alpha}\left(Z_{1}\right)>E S_{\alpha}\left(Z_{2}\right) \tag{28}
\end{equation*}
$$

Assuming $\theta_{1}=\theta_{2}$ and $p_{1}=p_{2}=p$ for simplification, we obtain the following condition from (27) and (28):

$$
\begin{equation*}
\frac{\sigma_{1}}{\sigma_{2}}>\bar{\kappa}_{E S}, \text { where } \bar{\kappa}_{E S}=\frac{1-\xi_{1}}{1-\xi_{2}}\left(\frac{1+\left((p / \alpha)^{\xi_{2}}-1\right) / \xi_{2}}{1+\left((p / \alpha)^{\xi_{1}}-1\right) / \xi_{1}}\right) \text {. } \tag{29}
\end{equation*}
$$

Table 6 shows the value of $\bar{\kappa}_{E S}$ with varying $\left(\xi_{1}, \xi_{2}\right)$ for expected shortfall at the $95 \%$ and $99 \%$ confidence levels, when $p$ is 0.05 and $0.1 .{ }^{24}$ This table shows that the conditions for the tail risk of expected shortfall are stricter than those for the tail risk of VaR. This confirms the result of Yamai and Yoshiba (2002c) that expected shortfall has no tail risk under more lenient conditions than VaR.

To summarise, VaR and expected shortfall may underestimate the risk of securities with fat-tailed properties and a high potential for large loss. The condition for tail risk to emerge depends on the parameters of the loss distribution and the confidence level.

## 5. The tail risk under multivariate extreme value distribution

The use of risk measures may lead to a failure of risk management when they fail to consider the change in dependence between asset returns. The credit portfolio example in Section 2.A shows that VaR disregards the increase in default correlation and thus fails to note the high potential for extreme loss in concentrated credit portfolios. In this case, the use of VaR for credit portfolios may lead to credit concentration.

In this section, we examine whether VaR and expected shortfall disregard the changes in dependence under a multivariate extreme value distribution. As the multivariate extreme value distribution, we use the joint distribution of exceedances introduced in Section 3.C. The marginal of this distribution is the

[^9]generalised Pareto and its copula is the Gumbel copula. We also use the Gaussian and Frank copulas for the copulas of exceedances for the case where the exceedances are asymptotically independent.

## A. The difficulty of applying multivariate extreme value distribution to risk measurement

The application of multivariate extreme value distribution to financial risk measurement has some problems that the univariate application does not. In the univariate case, the model for exceedances enables us to calculate VaR and expected shortfall as in Section 4. This is because the VaR and expected shortfall of exceedances are equal to the VaR and expected shortfall of the original loss data. However, in the multivariate case, the model for exceedances is not sufficient to calculate VaR and expected shortfall. This is because, in the multivariate case, the sum of exceedances is not necessarily equal to the exceedances of the sum. To calculate VaR and expected shortfall, we need the exceedances of the sum, which are unavailable from the model for exceedances alone. ${ }^{25,26,27}$
A simple example illustrates this point (Figure 9). Let $\left(U_{1}, U_{2}\right)$ denote a vector of independent standard uniform random variables. With a threshold value of $\left(\theta_{1}, \theta_{2}\right)=(0.9,0.9)$, the exceedances of $\left(U_{1}, U_{2}\right)$ are $\left(m_{0.9}\left(U_{1}\right), m_{0.9}\left(U_{2}\right)\right)=\left(\max \left(U_{1}, 0.9\right), \max \left(U_{2}, 0.9\right)\right)$. With the convolution theorem, the $95 \%$ upper quantile of $U_{1}+U_{2}$ is calculated to be 1.68 , while that of $m_{\theta_{1}}\left(U_{1}\right)+m_{\theta_{2}}\left(U_{2}\right)$ is calculated to be $1.88 .^{28}$ Thus, the sum of exceedances is larger than the exceedances of the sum.
This example shows that, to calculate VaR and expected shortfall in the multivariate case, we need a model for non-exceedances as well as one for exceedances.
In this paper, we assume that the marginal distribution of the non-exceedances is the standard normal distribution as we interpret the non-exceedances as asset loss under normal market conditions. That is, we assume that the marginal distribution is expressed by (30) below (Figure 10): ${ }^{29}$

[^10]\[

F(x)= $$
\begin{cases}\Phi(x) & \left(x<\Phi^{-1}(1-p)\right)  \tag{30}\\ 1-p\left(1+\xi \cdot \frac{x-\Phi^{-1}(1-p)}{\sigma}\right)^{-1 / \xi} & \left(x \geq \Phi^{-1}(1-p)\right) .\end{cases}
$$
\]

$\Phi \quad$ :the distribution function of the standard normal
$\Phi^{-1} \quad$ :the inverse function of $\Phi$
In the following analysis, we simulate two dependent asset losses to analyse the tail risk of VaR and expected shortfall. ${ }^{30}$ In the simulation, we assume that the marginal distribution of asset loss is (30). We also assume that the copula of asset loss is one of three copulas introduced in Section 3.E: Gumbel, Gaussian and Frank. We set the marginal distribution of each asset loss as identical so that we can examine the pure effect of dependence on the tail risk of VaR and expected shortfall. We limit our attention to the cases where the tail index is $0<\xi<1 .^{31}$

## B. One specific copula case

In this section, we assume that the change in the dependence structure of asset loss is represented by the change in the dependence parameters within one specific copula. Under this assumption, we examine whether VaR and expected shortfall consider the change in dependence by taking the following steps. First, we take one of the three copulas introduced in Section 3.E: Gumbel, Gaussian or Frank. Second, we simulate asset losses under the one copula for varied dependence parameter levels (Gumbel: $\alpha$, Gaussian: $\rho$, and Frank: $\delta$ ). Third, we calculate VaR and expected shortfall with the simulated asset losses for each dependence parameter level.
If VaR and expected shortfall do not increase with the rise in the level of dependence, VaR and expected shortfall disregard dependence and thus have tail risk.

Figure 11 shows an example of this analysis. The figure plots the empirical distribution of the sum of two simulated asset losses. These losses are simulated adopting (30) as the marginals and the Gumbel copula as the copula. The parameters of the marginal are set at $\xi=0.5, \sigma=1, p=0.1$, and the dependence parameter $\alpha$ of the Gumbel copula is set at $1.0,1.1,1.5,2.0$ and $\infty^{32}$ For each dependence parameter, we conduct one million simulations.

The result shows that the distribution tail gets fatter as the value of the dependence parameter $\alpha$ increases, or the asset losses are more dependent. Furthermore, the empirical distributions do not intersect with each other. This shows that the portfolio diversification effect works to decrease the risk of the portfolio and that VaR has no tail risk regardless of its confidence level.

Table 7 provides a more general analysis. The figure gives the VaR and expected shortfall under one million simulations for each copula with various dependence parameter levels. Two of the three marginal distribution parameters $(\xi, \sigma, p)$ are set at $\sigma=1, p=0.1$, and the tail index $\xi$ is set at 0.1 , $0.25,0.5$ and 0.75 . One of the copulas (Gumbel, Gaussian and Frank) is adopted. With these marginals and copulas, asset losses are simulated. VaR and expected shortfall are calculated for varied dependence parameter levels (Gumbel: $\alpha$, Gaussian: $\rho$, and Frank: $\delta$ ).

[^11]Table 7 shows that VaR and expected shortfall consider the change in dependence and have no tail risk in most of the cases. VaR and expected shortfall increase as the value of the dependence parameter rises, except for the Frank copula with extremely high dependence parameter levels. ${ }^{33}$

To summarise, $\operatorname{VaR}$ and expected shortfall have no tail risk when the change in dependence is represented by the change in parameters using one specific copula. Thus, if we select portfolios whose dependence structure is nested in one of the three copulas above, we can depend on VaR and expected shortfall for measuring dependent risks.

## C. Different copulas case

In the previous section, we assume that the change in the dependence of asset losses is represented by the change in the parameters using one specific copula. However, this assumption has a problem. One specific copula does not represent both asymptotic dependence and asymptotic independence.
Let us consider an example of this problem. Suppose we have two portfolios both composed of two securities. Also suppose that the security returns of one portfolio are asymptotically dependent while those of the other are asymptotically independent. Adopting one specific copula and changing the dependence parameters to describe the change in dependence does not work in this case. This is because one specific copula does not represent the change from asymptotic dependence to asymptotic independence. We need different types of copulas to compare asymptotic dependence with asymptotic independence.
In this section, we assume that the change in dependence is represented by the change in copula. We adopt the Gumbel, Gaussian and Frank copulas introduced in Section 3.E since the Gumbel copula corresponds to asymptotic dependence and the Gaussian and Frank copulas correspond to asymptotic independence. By changing copula from Gumbel to Gaussian and Frank, we can change the dependence structure from asymptotic dependence to asymptotic independence.
In comparing the results with three copulas, we set the values of the dependence parameters of those copulas (Gumbel: $\alpha$, Gaussian: $\rho$, and Frank: $\delta$ ) so that the Spearman's rho ( $\rho_{s}$ ) is equal across those copulas. ${ }^{34,35}$ By setting the Spearman's rho equal, we can eliminate the effect of global dependence and examine the pure effect of tail dependence since the Spearman's rho is a measure of global dependence.

The upper half of Figure 12 shows the empirical distributions of the sums of two simulated asset losses for the Gumbel, Gaussian and Frank copulas. This is generated from one million simulations for each copula where the parameters are fixed at $\xi=0.5, \sigma=1, \rho_{S}=0.5, p=0.1$. The range of the horizontal axis (cumulative probability) is above 99.5\%.
The tail shape of the loss distribution for each copula is consistent with the tail dependence of each copula. The empirical loss distribution for the Gumbel copula, which is asymptotically dependent
${ }^{33}$ In the case of the Frank copula, the VaR at the $95 \%$ confidence level when $\delta=\infty$ (full dependence) is smaller than the VaR when $\delta=9$.

This might be because the Frank copula has low tail dependence ( $\chi=\bar{\chi}=0$ ) and does not represent tail dependence when $\delta$ is large.
34 The Spearman's rho is the linear correlation of the marginals, and is defined by the following equation:
$\rho_{S}\left(Z_{1}, Z_{2}\right) \equiv \frac{\operatorname{Cov}\left(F_{Z_{1}}\left(Z_{1}\right), F_{Z_{2}}\left(Z_{2}\right)\right)}{\sqrt{V\left[F_{Z_{1}}\left(Z_{1}\right)\right] V\left[F_{Z_{2}}\left(Z_{2}\right)\right]}}$.
The Spearman's rho differs from $\chi$ and $\bar{\chi}$ in that it measures global dependence while $\chi$ and $\bar{\chi}$ measure tail dependence.
The Spearman's rho does not fully represent the dependence structures since the combination of the Spearman's rho and the marginal distribution does not uniquely define the joint distribution. In particular, it does not represent the asymptotic dependence measured by $\chi$ and $\bar{\chi}$. Nevertheless, the Spearman's rho is relatively superior as a single measure of global dependence (see Embrechts et al (2002)).
${ }^{35}$ We use the calculation in Joe (1997, p 147, Table 5.2) for the values of the dependence parameters that equate the Spearman's rho.
( $\chi>0, \bar{\chi}=1$ ), has the fattest tail. The empirical loss distribution for the Frank copula, which has the weakest tail dependence ( $\chi=0, \bar{\chi}=0$ ), has the thinnest tail. ${ }^{36}$

This shows that the potential for extreme loss is high when the tail dependence is high. Thus, if we are worried about extreme loss, portfolios with higher tail dependence should be considered more risky than those with lower tail dependence. As for the three copulas adopted here, we should consider the Gumbel copula as the most risky and the Frank copula the least risky in terms of tail risk. In this context, VaR and expected shortfall have tail risk when they do not increase in the order of Frank, Gaussian and Gumbel copulas.
The lower half of Figure 12 shows that VaR has tail risk in this example. The figure shows that the VaR at the $95 \%$ confidence level increases in the order of Gumbel, Gaussian and Frank. VaR says that the Gumbel copula is the least risky while the Frank copula is the most risky. This contradicts our observation of the upper tail described above.
Table 8 provides a more general analysis. The table shows the results of VaR and expected shortfall calculations for one million simulations for each copula with the tail index of the marginal distribution of $\xi=0.1,0.25,0.5$, and 0.75 , and Spearman's rho of $\rho_{s}=0.2,0.5$ and 0.8 .

The findings of the analysis are threefold. First, VaR and expected shortfall vary depending on the copula adopted. This means that the type of copula affects the level of VaR and expected shortfall. The difference is large when the tail index and the Spearman's rho are large.
Second, VaR at the $95 \%$ confidence level has tail risk when the tail index $\xi$ is 0.25 or higher. For example, when $\xi=0.5$ and $\rho_{s}=0.8$, the VaR at the $95 \%$ confidence level is largest for the Frank copula and smallest for the Gumbel copula. On the other hand, VaR at the $99 \%$ and $99.9 \%$ confidence level has no tail risk, except when the tail is as fat as $\xi=0.75$.

Third, expected shortfall has no tail risk at the 95, 99, or 99.9\% confidence level, except when the tail is as fat as $\xi=0.75$. This confirms the result of Yamai and Yoshiba (2002c) that expected shortfall has no tail risk under more lenient conditions than VaR.

## D. Different marginals case

In Sections 5.B and 5.C, the marginal distributions are assumed to be identical. In financial data, however, the distributions of asset returns are rarely identical. In this section, we extend our analysis to the different marginals case. We examine whether the conclusions in Sections 5.B and 5.C are still valid when the marginal distributions are different.

## 1. Independence vs full dependence case

We examine whether the results in Section $5 . B$ (the specific copula case) are still valid when the marginal distributions are different. We compare independence and full dependence, noting the fact that independence and full dependence are nested in the Gumbel, Gaussian and Frank copulas. When the VaR for independence is higher than the VaR for full dependence, VaR has tail risk.
We simulate independent and fully dependent asset losses with all combinations of parameters of the marginal distributions from $\xi_{1}=0.1,0.25,0.5,0.75, \xi_{2}=0.1,0.25,0.5,0.75, \sigma_{1}=1, \sigma_{2}=1.00,1.25$, $1.5, \ldots, 9.5,9.75,10$. We set the number of simulations at one million for each parameter combination. We calculate VaR and expected shortfall for both independence and full dependence, and compare them to see whether they have tail risk. We adopt the tail probability of $p=0.1$.
We found that the VaR for full dependence is never smaller than the VaR for independence. ${ }^{37}$ Thus, at least within this framework, VaR captures full dependence and independence when the marginal distributions are different.

[^12]
## 2. Different copulas case

We next examine whether the results in Section 5.B (the different copulas case) are still valid when the marginal distributions are different. We follow the same steps as in Section 5.C except that we set different parameter levels for two marginal distributions.

Under each one of the three copulas, as in Section 5.B, we simulate asset losses following the same method used in the previous subsection.

We find that VaR at the $95 \%$ confidence level may have tail risk even when the distribution tail is not so fat as $\xi=0.25 .^{38}$ This means that the conditions of the tail risk of VaR are more lenient when the marginals are different than when they are identical. Table 9 shows that, with a tail index of $\xi=0.1$, VaR at the $95 \%$ confidence level has tail risk. VaR is larger for the Gaussian copula than for the Gumbel copula. ${ }^{39}$

On the other hand, at the confidence level of $99 \%$, we find that VaR has tail risk only when the tail is as fat as $\xi=0.75$.

## 6. Empirical analyses

In Sections 4 and 5, we examine the tail risk of VaR and expected shortfall under extreme value distributions. We summarise the results as follows.

In the univariate case, VaR and expected shortfall may underestimate the risk of securities with fat-tailed properties and a high potential for large losses. The conditions for this to happen are expressed by a simple analytical inequality.

In the multivariate case, VaR and expected shortfall may both disregard the tail dependence when the tails of the marginal distributions are fat.

In this section, we conduct empirical analyses with exchange rate data to confirm whether VaR and expected shortfall have tail risk in actual financial data. We focus on the following questions.

Do VaR and expected shortfall underestimate the risk of currencies with fat-tailed properties and a high potential for large losses in the univariate case?

Is there asymptotic dependence that may bring the tail risk of VaR and expected shortfall in the multivariate case?

## A. Data

The data used for the analyses are the daily logarithmic changes of exchange rates of three industrialised countries and 18 emerging economies. ${ }^{40,41,42}$ The raw historical data are the exchange rates per one US dollar from 1 November 1993 to 29 October 2001.

[^13]
## B. Univariate analyses

We estimate the parameters of the generalised Pareto distribution on the daily exchange rate data. ${ }^{43}$ We use the maximum likelihood method described in Embrechts et al (1997), and Coles (2001). We vary the tail probability as $1 \%, 2 \%, \ldots, 10 \%$, and estimate the parameters $\xi$, $\sigma$, and $\theta$ for each. We then calculate the VaR and expected shortfall at the confidence levels of $95 \%$ and $99 \%$ using the estimated parameter values.

Table 10 shows the estimation results, and these findings may be summarised as follows. First, the tail indices are higher for the emerging economies (especially those in Asia and South America) than for the developed countries. In other words, the distribution tails are fatter in the emerging economies than in the developed countries.
Second, the scale parameter $(\sigma)$ is smaller in the emerging economies than in the developed countries. This suggests that the condition for tail risk derived in Section 4 may hold.

Third, VaR has tail risk in comparing the risk of some emerging economies and some developed countries. For example, let us compare the VaR for Japan and those for emerging economies. ${ }^{44}$ The VaR at the $95 \%$ confidence level for all the emerging economies except for Indonesia and Brazil is smaller than that for Japan. Even the VaR at the $99 \%$ confidence level is smaller for 10 emerging economies (Hong Kong, Singapore, Taiwan, Hungary, Poland, Slovakia, Chile, Columbia, Peru and Venezuela) than that for Japan.
Fourth, expected shortfall also has tail risk in comparing the risk of some emerging economies and some developed countries. For example, the expected shortfall at the $99 \%$ confidence level is smaller for six emerging economies (Hong Kong, Singapore, Taiwan, Chile, Columbia and Peru) than for Japan. ${ }^{45}$

Fifth, expected shortfall has tail risk in fewer cases than VaR. This is consistent with our findings in Section 4.

## C. Bivariate analyses (an example)

We provide an example where VaR has tail risk in actual exchange rate data in the bivariate case. We pick five currencies in Southeast Asian countries: the Indonesian rupiah, the Malaysian ringgit, the Philippine peso, the Singapore dollar and the Thai baht.

First, we estimate the parameters of the bivariate extreme value distribution introduced in Section 3. We adopt the same method as Longin and Solnik (2001). As in the analyses in Sections 4 and 5, we assume that the marginal distributions of bivariate exceedances are approximated by the generalised Pareto distribution (the distribution of exceedance as in (4), to be exact) and that their copula is approximated by the Gumbel copula. ${ }^{46}$ Given tail probabilities $p_{1}$ and $p_{2}$, the joint bivariate distribution of exceedances is described by the following parameters: the tail indices of the marginals ( $\xi_{1}$ and $\xi_{2}$ ), the scale parameters of the marginals ( $\sigma_{1}$ and $\sigma_{2}$ ), the thresholds ( $\theta_{1}$ and $\theta_{2}$ ), and the dependence parameter of the Gumbel copula ( $\alpha$ ).
We estimate those parameters on the right tails of each pair of Southeast Asian currencies by the maximum likelihood method ${ }^{47}$ for the tail probability of $10 \%$. Table 11 shows the results of the estimation.

[^14]After the estimation, we examine whether VaR and expected shortfall disregard tail dependence with the estimated parameter levels. We take the same step as in Section 5.C. First, we simulate the logarithm changes in exchange rates with the distribution of exceedances and the Gumbel copula, using the parameter levels estimated here. Second, we also simulate the logarithm changes in exchange rates with the Gaussian and Frank copulas. The dependence parameters for the Gaussian and Frank copulas are set so that the Spearman's rho $\left(\rho_{s}\right)$ is equal to that of Gumbel copula with the dependence parameter $\alpha$ at the estimated level. Third, we calculate the VaR and expected shortfall of the sums of the logarithm changes in two exchange rates. We run ten million simulations for each case.

Table 12 shows the result of those simulations. We find that the VaR at the $95 \%$ confidence level has tail risk for each pair of Southeast Asian currencies since the VaRs are larger for the Gaussian copula than for the Gumbel copula. Thus, VaR may disregard tail dependence in actual financial data. On the other hand, the VaR at the 99\% confidence level and the expected shortfall at the 95\% and 99\% confidence levels have no tail risk in this example.

## 7. Conclusions and implications

This paper shows that VaR and expected shortfall have tail risk under extreme value distributions. In the univariate case, VaR and expected shortfall may underestimate the risk of securities with fat-tailed properties and a high potential for large losses. In the multivariate case, VaR and expected shortfall may disregard the tail dependence.

The tail risk is the result of the interaction among various factors. These include the tail index, the scale parameter, the tail probability, the confidence level and the dependence structure.

These findings imply that the use of VaR and expected shortfall should not dominate financial risk management. Dependence on a single risk measure has a problem in disregarding important information on the risk of portfolios. To capture the information disregarded by VaR and expected shortfall, it is essential to monitor diverse aspects of the profit/loss distribution, such as tail fatness and asymptotic dependence.

The findings also imply that the widespread use of VaR for risk management could lead to market instability. ${ }^{48}$ Basak and Shapiro (2001) show that when investors use VaR for their risk management, their optimising behaviour may result in market positions that are subject to extreme loss because VaR provides misleading information regarding the distribution tail. They also note that such investor behaviour could result in higher volatility in equilibrium security prices. This paper shows that, under extreme value distribution, VaR may provide misleading information regarding the distribution tail.

Table 1
Sample portfolio payoff

| Portfolio A |  |  | Portfolio B |  |  |
| :---: | :---: | :---: | :---: | :---: | :---: |
| Payoff | Loss | Probability | Payoff | Loss | Probability |
| 100 | -2.95 | $50.000 \%$ | 98 | -0.95 | $50.000 \%$ |
| 95 | 2.05 | $49.000 \%$ | 97 | 0.05 | $49.000 \%$ |
| 50 | 47.05 | $1.000 \%$ | 90 | 7.05 | $0.457 \%$ |
|  |  |  | 20 | 77.05 | $0.543 \%$ |

Note: The probability that Portfolio B has a payoff of 90 or 20 is rounded off, and not precisely expressed. The model is set so that the sum of the probabilities of these payoffs is $1 \%$ and the expected payoff is 97.05 .

Table 2

## Sample portfolio VaR and expected shortfall

|  | Portfolio A | Portfolio B |
| :--- | :---: | :---: |
| Expected payoff | 97.05 | 97.05 |
| VaR (confidence level: 99\%) | 47.05 | 7.05 |
| Expected shortfall (confidence level: 99\%) | 47.05 | 45.05 |

Figure 3
Distribution of exceedances with varied tail indices

Note: Where the tail probability is $p=0.1$, the threshold value is $\theta=0$, and the scale parameter is $\sigma=1$.

Figure 4
Distribution of exceedances with varied scale parameters

Note: Where the tail probability is $p=0.1$, the threshold value is $\theta=0$, and the tail index is $\xi=0.25$.

Figure 5
Image diagram of bivariate exceedances

Note: The white circles represent the values of the underlying bivariate data and the black circles represent their exceedances. Source: Based on Reiss and Thomas (2000), Figure 10.1

Table 3
Asymptotic dependence and dependence measures $\chi$ and $\bar{\chi}$

|  | Independent | Asymptotically <br> independent | Asymptotically <br> dependent |
| :--- | :---: | :---: | :---: |
| $\chi$ | $\chi=0$ | $\chi=0$ | $0<\chi \leq 1$ |
| $\bar{\chi}$ | $\bar{\chi}=0$ | $-1<\bar{\chi}<1$ | $\bar{\chi}=1$ |
| Reference | Represented by the <br> extreme value copula | Not represented by the <br> extreme value copula | Represented by the <br> extreme value copula |

Note: When independent, $\bar{\chi}=0$. But the reverse is not necessarily true.

Table 4
Properties of the copulas used in this paper

| Equation | Dependence structure | $\chi$ | $\bar{\chi}$ |  |
| :--- | :---: | :---: | :---: | :---: |
| Gumbel | $C(u, v)=\exp \left\{-\left[(-\log u)^{\alpha}+(-\log v)^{\alpha}\right]^{1 / \alpha}\right\}$ | Independent when $\alpha=1$ <br> Fully dependent when <br> $\alpha=\infty$ | $\chi=2-2^{1 / \alpha}(\alpha \geq 1)$ | $\bar{\chi}=1$ |
| Gaussian | $C(u, v)=\Phi_{\rho}\left(\Phi^{-1}(u), \Phi^{-1}(v)\right)$ | Independent when $\rho=0$ <br> Fully dependent when <br> $\rho= \pm 1$ | $\chi=0(-1<\rho<1)$ | $\bar{\chi}=\rho$ |
| Frank | $C(u, v)=-\frac{1}{\delta} \ln \left(\frac{1-e^{-\delta}-\left(1-e^{-\delta u}\right)\left(1-e^{-\delta v}\right)}{1-e^{-\delta}}\right)$ | Independent when $\delta=0$ <br> Fully dependent when <br> $\delta= \pm \infty$ | $\chi=0$ | $\bar{\chi}=0$ |

Note: VaR and expected shortfall are calculated from one million simulations for each copula with the marginal distribution parameters set at $\sigma=1, p=0.1$. The tail index values are shown in the upper left of each table.

Figure 12
Empirical distributions under Gumbel, Gaussian and Frank copulas
(Portion with a cumulative probability of at least 99.5\%)

Note: The marginal distribution parameters are set at $\xi=0.5, \sigma=1, p=0.1$. The empirical distributions are generated by conducting one million simulations for each copula. For all of the copula parameters, the Spearman's rho is set at $\rho_{S}=0.5$.

Note: The exchange rate data are sourced from Bloomberg. The estimation period is 1 November 1993-29 October 2001.
The values of $\xi$ and $\sigma$ under the generalised Pareto distribution are estimated with the maximum likelihood estimation on the exceedances of daily logarithm changes in the exchange rates. VaR and expected shortfall are calculated using each of the estimated parameters.

Table 11
Estimation of the bivariate extreme value distribution of daily log changes
of the Southeast Asian exchange rates

Note: The exchange rate data are sourced from Bloomberg. The estimation period is 1 November 1993-29 October 2001.
The estimation is for the right tails of the logarithm changes. The tail probabilities are set at $p_{1}=p_{2}=0.1$.

## Appendix A: Copula of multivariate exceedances

This appendix explains the finding of Ledford and Tawn (1996) that the copula of multivariate exceedances converges to the extreme value copula.
We consider the copula of multivariate maxima before considering the copula of multivariate exceedances. The following theorem gives the foundations for describing the asymptotic joint distribution of multivariate maxima (see Resnick (1987), Proposition 5.11 for the proof).

## Theorem

Suppose that $\left\{\left(Z_{1 j}, Z_{2 j}\right) ; j=1, \ldots, n\right\}$ are independent and identically distributed two-dimensional random vectors with the joint distribution function $F$. Also suppose that the marginal distribution of these two-dimensional random vectors is a Fréchet distribution. In other words, for each $i, j$, $\operatorname{Pr}\left[Z_{i j} \leq z_{i j}\right]=\exp \left(-1 / z_{i j}\right)$. Define the vector of component-wise maxima as $M_{Z_{i}, n}=\max \left(Z_{i 1}, Z_{i 2}, \ldots, Z_{i n}\right)$. Then, the following holds:
$\operatorname{Pr}\left[\frac{M_{z_{1, n}}}{n} \leq z_{1}, \frac{M_{z_{2, n}}}{n} \leq z_{2}\right]=F^{n}\left(n z_{1}, n z_{2}\right) \rightarrow G\left(z_{1}, z_{2}\right)$, as $n \rightarrow \infty$,
where $G\left(z_{1}, z_{2}\right)=\exp \left\{-V\left(z_{1}, z_{2}\right)\right\}$,

$$
V\left(z_{1}, z_{2}\right)=\int_{0}^{1} \max \left\{s z_{1}^{-1},(1-s) z_{2}^{-1}\right\} d H(s) .
$$

$H$ is a non-negative measure on $[0,1]$ that satisfies the following condition:
$\int_{0}^{1} s d H(s)=\int_{0}^{1}(1-s) d H(s)=1$.
Using this theorem, Ledford and Tawn (1996) show that the copula of multivariate exceedances converges to the bivariate extreme value copula as follows.

Suppose that $\left\{\left(Z_{1 j}, Z_{2 j}\right) ; j=1, \ldots, n\right\}$ are independent and identically distributed two-dimensional random vectors with the joint distribution function $F_{\star}$. Also assume that the marginal distribution of $\left(Z_{1}, Z_{2}\right)$ is a Fréchet distribution. In other words, for each $i, \operatorname{Pr}\left[Z_{i} \leq z_{i}\right]=\exp \left(-1 / z_{i}\right)$. Based on Proposition 5.15 in Resnick (1987), $F_{*}$ is within the domain of attraction of $G_{*}$ if and only if the following holds:

$$
\begin{equation*}
\lim _{t \rightarrow \infty} \frac{-\log F_{*}\left(t z_{1}, t z_{2}\right)}{-\log F_{*}(t, t)}=\frac{-\log G_{*}\left(z_{1}, z_{2}\right)}{-\log G_{*}(1,1)} . \tag{A-1}
\end{equation*}
$$

As this is an asymptotic result, Ledford and Tawn (1996) assume that this also holds with a sufficiently large value of $t=t_{c}$. That is, the following holds for a large value of $t=t_{c}$ :

$$
\begin{equation*}
\frac{-\log F_{\star}\left(t_{c} z_{1}, t_{c} z_{2}\right)}{-\log F_{*}\left(t_{c}, t_{c}\right)}=\frac{-\log G_{*}\left(z_{1}, z_{2}\right)}{-\log G_{*}(1,1)} . \tag{A-2}
\end{equation*}
$$

Define $z_{j}^{\prime}$ as $z_{j}^{\prime}=t_{c} z_{j}$. With (A-2), the following holds when $z_{j}^{\prime}$ is above some high threshold $\theta_{j}$ :
$\log F_{\star}\left(z_{1}^{\prime}, z_{2}^{\prime}\right)=\log F_{\star}\left(t_{c}, t_{c}\right) \frac{\log G_{*}\left(z_{1}^{\prime} / t_{c}, z_{2}^{\prime} / t_{c}\right)}{\log G_{*}(1,1)}$.
$G_{*}$ satisfies the following condition since $G_{*}$ is the extreme value distribution,
$G\left(z_{1}^{\prime}, z_{2}^{\prime}\right)=\exp \left\{-V\left(z_{1}^{\prime}, z_{2}^{\prime}\right)\right\}$,
where $V\left(z_{1}, z_{2}\right)=\int_{0}^{1} \max \left\{s z_{1}^{-1},(1-s) z_{2}^{-1}\right\} d H(s)$.
Here, $H$ is a non-negative measure on $[0,1]$ that satisfies $\int_{0}^{1} s d H(s)=\int_{0}^{1}(1-s) d H(s)=1$.
As $V$ is a homogeneous function of order -1 , this leads to the following relation (where $z^{\prime}$ is now expressed by $z$ ).

$$
\begin{equation*}
F_{\star}\left(z_{1}, z_{2}\right)=\exp \left\{V\left(z_{1}, z_{2}\right) \frac{t_{c} \log F_{\star}\left(t_{c}, t_{c}\right)}{V(1,1)}\right\}=\exp \left\{V\left(z_{1}, z_{2}\right) K\right\} \tag{A-5}
\end{equation*}
$$

where $K$ is a constant.
To determine the value of $K$ we consider the value of $F_{*}$ at the threshold $\theta_{j}$. If we suppose that this threshold value is the $1-\lambda_{j}$ quantile, $\theta_{j}$ is derived as $\theta_{j}=-1 / \log \left(1-\lambda_{j}\right)$. Setting $z_{1}=\theta_{1}=-1 / \log \left(1-\lambda_{1}\right)$ and $z_{2}=\infty$ in (A-5), we obtain the following:
$F_{*}\left(-1 / \log \left(1-\lambda_{1}\right), \infty\right)=\exp \left\{V\left(-1 / \log \left(1-\lambda_{1}\right), \infty\right) K\right\}$.
The left-hand side of equation (A-6) is equal to $1-\lambda_{1}$ because it is the distribution function at the $1-\lambda_{1}$ quantile. On the other hand, the right-hand side of equation $(A-6)$ is equal to $\exp \left\{-K \log \left(1-\lambda_{1}\right)\right\}$, as shown below:

$$
\begin{align*}
V\left(-1 / \log \left(1-\lambda_{1}\right), \infty\right) & =\int_{0}^{1} \max \left\{s\left(-\log \left(1-\lambda_{1}\right)\right),(1-s) / \infty\right\} d H(s)  \tag{A-7}\\
& =-\log \left(1-\lambda_{1}\right) \int_{0}^{1} s d H(s)=-\log \left(1-\lambda_{1}\right)
\end{align*}
$$

As $1-\lambda_{1}=\exp \left\{-K \log \left(1-\lambda_{1}\right)\right\}$, we find that $K=-1$. Setting this into $(\mathrm{A}-5), F_{\star}$ is obtained as follows:

$$
\begin{equation*}
F_{\star}\left(z_{1}, z_{2}\right)=\exp \left\{-V\left(z_{1}, z_{2}\right)\right\} \tag{A-8}
\end{equation*}
$$

where $V\left(z_{1}, z_{2}\right)$ is the same as in (A-4).
This shows that the asymptotic joint distribution of the multivariate exceedances whose marginal distribution is a Fréchet distribution is given by (A-8).

We use this result to obtain the copula of multivariate exceedances whose marginals are not Fréchet distributions. Define $u_{i}$ as $u_{i} \equiv \operatorname{Pr}\left[Z_{i} \leq z_{i}\right]=\exp \left(-1 / z_{i}\right)$. Set $z_{i}=-1 / \log u_{i}$ into $G\left(z_{1}, z_{2}\right)=\exp \left\{-V\left(z_{1}, z_{2}\right)\right\}$ to obtain the following copula:
$C\left(u_{1}, u_{2}\right)=\exp \left\{-V\left(-\frac{1}{\log u_{1}},-\frac{1}{\log u_{2}}\right)\right\}$,
where $V\left(z_{1}, z_{2}\right)$ is the same as (A-4).
With copula invariance, this is the copula of exceedances for all marginals since the copula is invariant under increasing continuous transformations. ${ }^{49}$

[^17]
## Appendix B: Tail risk of VaR under the generalised Pareto distribution

This appendix analyses the tail risk of VaR under the generalised Pareto distribution employing Feller's convolution theorem. ${ }^{50}$ We assume that the marginal distributions of asset losses are the generalised Pareto and have the same tail index.

This assumption is different from the assumption in Sections 3 and 4 in two aspects. First, in Sections 3 and 4, we assume that only the exceedances follow the generalised Pareto distribution. In this appendix, we assume that the both exceedances and non-exceedances follow the same generalised Pareto distribution. Second, in Sections 3 and 4, we assume that the tail index is different among assets. In this appendix, we assume that the tail index is equal across assets. Thus, under the assumption in Sections 3 and 4, we are unable to employ the convolution theorem used in this appendix.

Feller (1971, p 278) and Embrechts et al (1997, Lemma 1.3.1) utilise the convolution theorem for regularly varying distribution functions to examine the properties of the sum of the independent random variables with the same tail index. We explain their conclusions, incorporating our concept of tail risk.

Suppose that two independent random variables $Z_{1}$ and $Z_{2}$ have the same distribution functions as follows:

$$
\begin{equation*}
G_{\xi, \sigma}(x)=1-\left(1+\xi \cdot \frac{x}{\sigma}\right)_{+}^{-1 / \xi} . \tag{B-1}
\end{equation*}
$$

The distribution function of the sum of the two random variables $Z_{1}$ and $Z_{2}$ is derived from the convolution of equation (B-1), as follows:
$H(x) \equiv \operatorname{Pr}\left\{Z_{1}+Z_{2} \leq x\right\} \equiv \int_{0}^{x} G_{\xi, \sigma}(x-y) d G_{\xi, \sigma}(y)$.
The function $\bar{G}_{\xi, \sigma}(x) \equiv 1-G_{\xi, \sigma}(x)$ is transformed as follows:

$$
\begin{equation*}
\bar{G}_{\xi, \sigma}(x)=\left(1+\xi \cdot \frac{x}{\sigma}\right)_{+}^{-1 / \xi}=x^{-1 / \xi}\left(\frac{1}{x}+\frac{\xi}{\sigma}\right)_{+}^{-1 / \xi} . \tag{B-3}
\end{equation*}
$$

Since the term $(1 / x+\xi(x-\theta) / \sigma)_{+}^{-1 / 5}$ on the right-hand side of equation (B-3) is slowly varying, ${ }^{51}$ using Feller's convolution theorem (see Feller (1971, p 278), or Embrechts et al (1997, Lemma 1.3.1), the following relation holds when the value of $x$ is sufficiently large:

$$
\begin{equation*}
\bar{H}(x) \approx x^{-1 / \xi}\left\{\left(\frac{1}{x}+\frac{\xi}{\sigma}\right)_{+}^{-1 / \xi}+\left(\frac{1}{x}+\frac{\xi}{\sigma}\right)_{+}^{-1 / \xi}\right\}=2\left(1+\xi \cdot \frac{x}{\sigma}\right)_{+}^{-1 / \xi}, \tag{B-4}
\end{equation*}
$$

where $\bar{H}(x) \equiv 1-H(x)$. Therefore, the distribution function of the sum of two independent random variables $Z_{1}$ and $Z_{2}$ is as follows, when the value of $x$ is sufficiently large:
$H(x) \approx 1-2\left(1+\xi \cdot \frac{x}{\sigma}\right)_{+}^{-1 / \xi}$.

[^18]Meanwhile, the distribution function of the sum of two fully dependent random variables whose distribution function is given by ( $B-1$ ) follows the same distribution as $2 Z_{1}$. Thus, the distribution function $I(x)$ of the sum of two fully dependent variables is given below:

$$
\begin{equation*}
I(x) \equiv \operatorname{Pr}\left\{2 Z_{1} \leq x\right\}=\operatorname{Pr}\left\{Z_{1} \leq x / 2\right\}=G_{\xi, \sigma}(x / 2)=1-\left(1+\xi \cdot \frac{x}{2 \sigma}\right)_{+}^{-1 / \xi} \tag{B-6}
\end{equation*}
$$

VaR has tail risk when the two distribution functions $H(x)$ and $I(x)$ intersect (that is, when there is a solution to $H(x)=I(x)$ ), and when the VaR confidence level is lower than the cumulative probability of this intersection. In the case of $\xi<1$, there is a solution to $H(x)=I(x)$, and the cumulative probability $p(\xi)$ at the intersection is as follows: ${ }^{.52}$
$p(\xi)=1-2\left(1+\frac{2^{\xi}-1}{1-2^{\xi-1}}\right)^{-1 / \xi} \quad(\xi<1)$.
With some calculations (B-7), we find that the tail index must be 0.9 or higher for VaR to have tail risk at the confidence levels of $95 \%$ and $99 \%$.
The tail index is 0.9 or higher only when the distribution is so fat that the 1.2-th moment is infinite. Such a fat-tailed distribution is rarely found in financial data. Thus, under the assumptions of this appendix, we find that VaR does not have tail risk as long as the confidence level is sufficiently high.

[^0]:    1 The views expressed here are those of the authors and do not reflect those of the Bank of Japan. (E-mail: yasuhiro.yamai@boj.or.jp; toshinao.yoshiba@boj.or.jp.) This paper is a revised version of the paper presented at the Third Joint Central Bank Research Conference on Risk Measurement and Systemic Risk on 7-8 March 2002 in Basel. The content of this paper is the same as Yamai, Y and T Yoshiba, "Comparative analyses of expected shortfall and value-atrisk (3): their validity under market stress", IMES Discussion Paper No 2002-E-2, Bank of Japan, 2002.
    ${ }^{2} \mathrm{VaR}$ at the $100(1-\alpha) \%$ confidence level is the upper $100 \alpha$ percentile of the loss distribution. We denote the VaR at the $100(1-\alpha) \%$ confidence level as $\operatorname{VaR}_{a}(Z)$, where $Z$ is the random variable of loss.
    ${ }^{3}$ When the distributions of loss $Z$ are continuous, expected shortfall at the $100(1-\alpha) \%$ confidence level $\left(E S_{\alpha}(Z)\right)$ is defined by the following equation:

[^1]:    When the underlying distributions are discontinuous, see Definition 2 of Acerbi and Tasche (2001).
    4 Jorion (2000) makes the following comment in analysing the failure of Long-Term Capital Management (LTCM): "The payoff patterns of the investment strategy [of LTCM] were akin to short positions in options. Even if it had measured its risk correctly, the firm failed to manage its risk properly."

    5 Prior comparative analyses of VaR and expected shortfall focus on their sub-additivity. For example, Artzner et al (1997, 1999) show that expected shortfall is sub-additive, while VaR is not. Acerbi et al (2001) prove that expected shortfall is subadditive, including the cases where the underlying profit/loss distributions are discontinuous. Rockafeller and Uryasev (2000) utilise the sub-additivity of the expected shortfall to find an efficient algorithm for optimising expected shortfall.

    6 The other important aspect of the comparative analyses of VaR and expected shortfall is their estimation errors. Yamai and Yoshiba (2002b) show that expected shortfall needs a larger size sample than VaR for the same level of accuracy.
    7 For other financial applications of multivariate extreme value theory, see Longin and Solnik (2001), Embrechts et al (2000) and Hartmann et al (2000).
    8 We only consider whether VaR and expected shortfall are effective for the relative choice of portfolios. We do not consider the issue of the absolute level of risk, such as whether $\operatorname{VaR}$ is appropriate as a benchmark of risk capital.
    9 For details regarding the general concept and definition of the tail risk of risk measures, see Yamai and Yoshiba (2002c).

[^2]:    10 Lucas et al (2001) also develop more general analyses in their paper.
    11 The total exposure of the bond portfolio is 1 .

[^3]:    12 Yamai and Yoshiba (2002c) show that VaR has no tail risk when the loss distributions are of the same type of an elliptical distribution.

    13 For detailed explanations of extreme value theory, see Coles (2001), Embrechts et al (1997), Kotz and Nadarajah (2000) and Resnick (1987).

[^4]:    14 See Coles (2001) and Embrechts et al (1997) for a detailed explanation of this theorem.
    15 In this paper we assume that $\xi \neq 0$.
    16 For the precise definition of copula and proofs of the theorems adopted here, see eg Embrechts et al (2002), Joe (1997), Nelsen (1999) and Frees and Valdez (1998).
    17 The standard uniform distribution is the uniform distribution over the interval [0,1].

[^5]:    18 For more detailed explanations of multivariate extreme value theory, see Coles (2001) Ch 8 , Kotz and Nadarajah (2000) Ch 3, McNeil (2000), Resnick (1987) Ch 5, etc.

[^6]:    19 For other parameterised extreme value copulas, see, for example, Joe (1997) and Kotz and Nadarajah (2000).

[^7]:    ${ }^{20}$ This definition of the Frank copula follows Joe (1997).
    ${ }^{21}$ See Ledford and Tawn (1996, 1997), Coles et al (1999) and Hefferman (2000) for the definition and concepts of tail dependence, including the derivations of $\chi$ and $\bar{\chi}$ for each copula.

[^8]:    ${ }^{22}$ When the tail probability is $p=0.05$, the $\operatorname{VaR}$ at the confidence level of $95 \%$ is not beyond the threshold, so we do not calculate VaR at the confidence level of $95 \%$ when $p=0.05$.

[^9]:    ${ }^{23}$ The third equality is based on Embrechts et al (1997), Theorem 3.4.13 (e).
    ${ }^{24}$ We do not calculate expected shortfall at the confidence level of $95 \%$ when $p=0.05$ (see footnote 22).

[^10]:    25 This is also a problem when the model for maxima is used for calculating VaR and expected shortfall. This is because the sums of maxima are not necessarily equal to the maxima of sums. Hauksson et al (2000) and Bouyé (2001) propose the use of multivariate generalised extreme value distributions for financial risk measurement, but they do not address this problem.
    26 The quantile of the sum of exceedances is equal to that of the original data when the underlying random variables are fully dependent.
    ${ }^{27}$ McNeil (2000) says that multivariate extreme value modelling has the problem of "the curse of dimensionality". He notes that, when the number of dimension is more than two, the estimation of copula is not tractable.
    28 The upper $95 \%$ quantile of $U_{1}+U_{2}$ is calculated as follows. Denote the distribution function of $U_{1}+U_{2}$ as $G(x)$. Clearly, the upper $95 \%$ quantile of $U_{1}+U_{2}$ is greater than 1 . So assuming $x>1, G(x)$ is calculated by the convolution theorem as follows:
    $G(x)=\int_{0}^{1} \operatorname{Pr}\left[U_{1} \leq x-u\right] d u=-\frac{1}{2}(x-2)^{2}+1$
    The upper $95 \%$ quantile is $x$ that satisfies $G(x)=0.95$, which is calculated as $x \approx 1.6838$.
    The upper $95 \%$ quantile of the sum of the exceedances is calculated as follows. Define $H(x) \equiv \operatorname{Pr}\left[\max \left(U_{1}, 0.9\right)+\max \left(U_{2}, 0.9\right) \leq x\right]$. Using the convolution theorem, this is restated as follows:
    $H(x)=\int_{0}^{1} \operatorname{Pr}\left[\max \left(U_{1}, 0.9\right) \leq x-u\right] \cdot \operatorname{Pr}\left[\max \left(U_{2}, 0.9\right)=u\right] d u=\left\{\begin{array}{cl}x^{2} / 2-0.81 & (x \leq 1.9) \\ -(x-2)^{2} / 2+1 & (x>1.9)\end{array}\right.$
    The upper $95 \%$ quantile is $x$ that satisfies $G(x)=0.95$, which is calculated as $x \approx 1.8761$.
    29 A different assumption might be that the marginal distribution of exceedances is a non-standard normal distribution, a $t$-distribution, a generalised Pareto distribution, or an empirical distribution produced from actual data. Assuming a non-standard normal distribution, a $t$-distribution, and a generalised Pareto distribution, we simulated asset loss as in sections B and C of this chapter, and found the same result as in those sections. Furthermore, under the assumption of a generalised Pareto distribution, the convolution theorem is applied to obtain the analytics of the tail risk of VaR (see Appendix B for the details).

[^11]:    30 We use the Mersenne Twister for generating uniform random numbers, and the Box-Müller method for transforming the uniform random numbers into normal random numbers. We follow Frees and Valdez (1998) in simulating the Gumbel copula, and Joe (1997) for simulating the Gaussian and Frank copulas.
    ${ }^{31}$ The generalised Pareto distribution with $\xi>1$ is so fat-tailed that its mean is infinite (Embrechts et al (1997), Theorem 3.4.13 (a)).

    The generalised Pareto distribution with $\xi>1$ has several interesting properties. However, it is not considered in this paper because such a fat-tailed distribution is rarely observed in financial data. For details, see Appendix B.
    ${ }^{32}$ Under the Gumbel copula $\chi=2-2^{1 / \alpha}$, so the corresponding values of $\chi$ become $\chi=0,0.12,0.41,0.59,1$.

[^12]:    ${ }^{36}$ See Figure 7 for the values of $\chi$ and $\bar{\chi}$ for each copula.

[^13]:    ${ }^{37}$ The results of this simulation are omitted here due to space restrictions.
    38 See Footnote 37.
    39 This finding was confirmed by running 10 million simulations.
    40 The data are sourced from Bloomberg
    ${ }^{41}$ We set the exchange rate as constant over holidays at the levels of the previous business day. This treatment does not affect our results as we estimate only the tails of distributions.
    42 The currencies of developed countries are as follows: Japanese yen, the Deutsche mark and pound sterling. The currencies of emerging economies are as follows: Hong Kong dollar, Indonesian rupiah, Malaysian ringgit, Philippine peso, Singapore dollar, South Korean won, new Taiwan dollar, Thai baht, Czech koruna, Hungarian forint, Polish zloty, Slovakian koruna, Brazilian real, Chilean peso, Colombian peso, Mexican new peso, Peruvian new sol and Venezuelan bolívar.

[^14]:    ${ }^{43}$ The extreme value theory is applicable to a stationary process given that the process satisfies some condition. See Ch 5 of Coles (2001) for details.
    44 In the comparison here, we use the averages of the VaRs at the $95 \%$ confidence level in the right tail with the tail probabilities from $5 \%$ to $10 \%$, and the average of VaRs at the $99 \%$ confidence level in the right tail with the tail probabilities from 1\% to 10\%.
    45 In the comparison here, we use the average of the expected shortfalls at the $99 \%$ confidence level in the right tail with the tail probabilities from $1 \%$ to $10 \%$.
    46 Instead of using parametric technique, one is able to use non-parametric estimation techniques. See Capéraà et al (1997) for details.

    47 See Longin and Solnik (2001) and Ledford and Tawn (1996) for the construction of the maximum likelihood function.

[^15]:    ${ }^{48}$ See Dunbar (2001) for the practitioners' view on this argument.

[^16]:    Note: VaR and expected shortfall are calculated from one million simulations for each copula with the marginal distribution

[^17]:    49 Proposition 5.10 in Resnick (1987) shows that this approach is appropriate.

[^18]:    50 Geluk et al (2000) adopt Feller's convolution theorem for analysing the portfolio diversification effect under fat-tailed distributions.

    51 Slowly varying functions are those functions $L(x)$ that satisfy the following condition (see Feller (1971) for details):
    $\lim _{x \rightarrow \infty} \frac{L(t x)}{L(x)}=1$

[^19]:    52 When $\xi \geq 1$, VaR is not sub-additive and has no tail risk. As $H(x)<I(x)$ for all $x$, the VaR for independence is larger than the VaR for full dependence. This shows that VaR is not sub-additive. On the other hand, full dependence dominates independence in the first order stochastic dominance. Thus, the ordering by VaR is consistent with the ordering by the first order stochastic dominance.
