An Equilibrium Model of "Global Imbalances" and Low Interest Rates

Ricardo J. Caballero   Emmanuel Farhi   Pierre-Olivier Gourinchas*

This Draft: April 26, 2006

Abstract

Three of the most important recent facts in global macroeconomics — the sustained rise in the US current account deficit, the stubborn decline in long run real rates, and the rise in the share of US assets in global portfolio — appear as anomalies from the perspective of conventional wisdom and models. Instead, in this paper we provide a model that rationalizes these facts as an equilibrium outcome of two observed forces: a) potential growth differentials among different regions of the world and, b) heterogeneity in these regions' capacity to generate financial assets from real investments. In extensions of the basic model, we also generate exchange rate and FDI excess returns which are broadly consistent with the recent trends in these variables. Unlike the conventional wisdom, in the absence of a large change in (a) or (b), our model does not augur any catastrophic event. More generally, the framework is flexible enough to shed light on a range of scenarios in a global equilibrium environment.

JEL Codes: E0, F3, F4, G1

Keywords: Current account deficits, capital flows, interest rates, global portfolios and equilibrium, growth and financial development asymmetries, exchange rates, FDI, intermediation rents.

1 Introduction

Three facts have dominated the discussion in global macroeconomics in recent times:

Fact 1: The US has run a persistent current account deficit since the early 1990s, which has accelerated dramatically since the late 1990s. Today, it exceeds US$600 billions a year. The solid dark line in Figure 1(a) illustrates this path, as a ratio of World's GDP (this line also includes the deficits of the U.K. and Australia, for reasons that will be apparent below, but it is overwhelmingly dominated by the U.S. pattern). The counterpart of these deficits has been driven by the surpluses in Japan and Continental Europe throughout the period and, starting at the end of the 1990s, by the large surpluses in Asia ex-Japan, commodity producers, and the turnaround of the current account deficits in most non-European emerging market economies.

Fact 2: The long run real interest rate has been steadily declining over the last decade, despite recent efforts from central banks to raise interest rates (the "Greenspan's Conundrum"). See Figure 1(b).

Fact 3: The importance of US assets in global portfolios has increased throughout the period and now amounts to over 17 percent of the rest of the world's financial wealth, which is equivalent to 43 percent of their annual output. See Figure 1(c).

Despite extensive debates on the factors behind and sustainability of this environment, there are very few formal structures to analyze these joint phenomena. The conventional view and their recent formalizations, attempt mostly to explain (the first half of) fact 1, largely ignore fact 2, and take 3 as an exogenous anomaly. The analysis about the future then consists of telling the story that follows once this "anomaly" goes away. However, capital flows are primarily an asset market phenomenon and hence the paths of interest rates and portfolios must be made an integral part of the analysis if we are to conjecture on what got the world into the current situation and how it is likely to get out of it.[1]

The main purpose of this paper is to provide a framework to analyze global equilibrium and, as an important side product, shed some light on the above facts. The model is fairly standard in its ingredients and provides a simple asset-demand and (most importantly) -supply framework to characterize the impact of different shocks on global capital flows, interest rates and portfolios. We use this model to show that the patterns in Figure 1 (together with observed exchange rate and gross flows patterns) can arise naturally from observed growth and financial market shocks, which interact with heterogeneous degrees of financial market development in different regions of the world.

We divide the world into three groups: The US (and "similar" economies such as Australia and the U.K.) (U); the EuroZone/Japan (E); and the rest (R). The latter include emerging markets, oil producing countries, and high saving newly industrialized economies, such as Hong-Kong, Singapore and Korea. Both U and E produce good quality financial instruments. R, on the other hand, has high growth potential but

---

[1]Recently, some of the debate in policy circles also has began to highlight the role of equilibrium in global capital markets for US current account deficits. See especially Bernanke (2005) and IMF (2005). We will revisit the "saving glut" view after we have developed our framework.

Professional Forecasters. (c) World Development Indicators, Bureau of Economic Analysis, European Central Bank, Bank of
Japan and Authors' calculations (see appendix)

has episodes when it cannot generate "enough" reliable savings instruments.[2]

In this world, we investigate the implication of a growth slowdown in E and, primarily, a collapse in asset markets in R. We show that both shocks point in the same direction, in terms of generating a rise in capital flows toward U, a decline in real interest rates, and an increase in the importance of U's assets in global portfolios. Importantly, while there are natural forces that undo some of the initial trade deficits in U, these are tenuous, as U's current account never needs to turn into surplus and capital flows indefinitely toward U.

The key feature of the model is that it focuses on the regions' ability to *supply* financial assets to savers. Regions U and E compete on asset production. Region R demands financial assets. Thus, fast growth in R coupled with their inability to generate local store of value instruments increases their demand for saving instruments from U and E. More growth potential in U than in E means that a larger share of global saving flows to U.

In the basic model productive assets are fixed and (implicitly) run by local agents, and there is a single good. We relax these assumptions in extensions. In the first one we allow for an investment margin and a reason for foreign direct investment (FDI). These additions enrich the framework along two important dimensions in matching the facts: First, the collapse in asset markets in R can lead to an investment slump in R (as opposed to just an increase in saving rates) which exacerbates the results from the basic model. Second, the intermediation rents from FDI, whose main reason is to transfer "corporate governance" from one country to another, reduce the trade surpluses that U needs to generate to repay for its persistent early deficits. In some instances, these rents allow U to finance permanent trade deficits.

In the second extension we allow for heterogeneous goods and discuss (real) exchange rate determination. The exchange rate patterns generated by the expanded model in response to the shocks highlighted above are broadly consistent with those observed in the data —in particular, U appreciates vis a vis both, R and E— and anticipate a very limited and slow depreciation of U's exchange rate in the absence of further shocks.

There are several recent articles related to the $U - E$ analysis in our paper. For instance, Blanchard, Giavazzi and Sa (2005) analyzes US external imbalances from the point of view of portfolio balance theory à la Kouri (1982). Their approach takes world interest rates as given and focuses on the dual role of the exchange rate in allocating portfolios between imperfectly substitutable domestic and foreign assets and relative demand through the terms of trade. In their model, the large recent US current account imbalances result from exogenous increases in U.S. demand for foreign goods and in foreign demand for U.S. assets. Their model predicts a substantial future depreciation of the US dollar since the exchange rate is the only equilibrating variable and current account deficits must be reversed. Obstfeld and Rogoff (2004) and (2005)

---

[2]See Caballero and Krishnamurthy (2006) for a model of bubbles in emerging markets as a result of their inability to generate reliable financial assets. When local bubbles crash, countries need to seek store of value abroad. This pattern also could arise from a fundamental shock due to a change in public perception of the soundness of the financial system and local conglomerates, degree of "cronysm," and so on.

consider an adjustment process through the global reallocation of demand for traded versus non traded and domestic versus foreign goods. Their analysis takes as given that a current account reversal needs to occur in the US, as well as the levels of relative supply of traded and non-traded goods in each country. Because the current account deficits represents a large share of traded output, they too, predict a large real depreciation of the dollar. These papers differ from ours in terms of the shocks leading to the current "imbalances", our emphasis on equilibrium in global financial markets and, most importantly, on the connection between this equilibrium and the countries' ability to produce sound financial assets.

For the $U - E$ part, the closest paper in terms of themes and some of the implications is Caballero, Farhi and Hammour (forthcoming 2006), who present several models of speculative investments booms in U and low global interest rates. One of the mechanisms they discuss is triggered by a slowdown in investment opportunities in E. However the emphasis in that paper is on the investment side of the problem and ignores the role of R and asset supply, which are central to our analysis in this paper. Kraay and Ventura (forthcoming 2006) analyze an environment similar to that in Caballero et al.. Their emphasis is on the allocation of excess global savings to a US bubble but it does not connect capital flows to growth and domestic financial markets fundamentals as we do here. Finally, Cooper (2005) presents a view about the U-E region similar to ours in terms of substantive conclusions.

For the $U - R$ part, Dooley, Folkerts-Landau and Garber (2003) and Dooley and Garber (forthcoming 2006) have argued that the current pattern of US external imbalances does not represent a threat to the global macroeconomic environment. Their "Bretton Woods II" analysis states that the structure of capital flows is optimal from the point of view of developing countries trying to maintain a competitive exchange rate, to develop a productive traded good sector, or to absorb large amounts of rural workers in the industrial sector. Unlike theirs, our analysis emphasizes the role of private sector capital flows and argues that the exchange rate is mostly a sideshow.[3]

Section 2 is the core of the paper and presents the main model and mechanisms. Section 3 introduces an investment margin and a reason for FDI, while Section 4 analyzes exchange rate determination. Section 5 discusses the impact of reversals in growth and financial development differentials. Section 6 concludes and is followed by several appendices.

---

[3]We do not deny the existence of large reserves accumulation by China and others. Nonetheless, we make three observations. First, most of these reserves are indirectly held by their local private sectors through (quasi-collateralized) low-return sterilization bonds in a context with only limited capital account openness. Second, US gross flows are an order of magnitude larger than official flows – rather than imputing Chinese reserves accumulation to financing the US current account deficit, one could equally well (or poorly) argue that they are financing FDI flows to emerging markets, including China. Third, the role of official interventions was most important at a time when the US was experiencing a temporary slowdown, while our analysis refers to more persistent trends.

2 A Model with Explicit Asset Supply Constraints

In this section we develop a stylized model that endogenizes and captures the broad patterns of capital flows, interest rates and global portfolios shown in Figure 1. The model highlights the supply side of the market for global saving instruments. We slice the world into three groups: U-countries have deep financial markets and good growth conditions; E-countries have deep financial markets but (perhaps temporarily) bad growth conditions; finally, R-countries (perhaps temporarily) do not have deep financial markets but have exceptional growth conditions.

In this context we show that both the depressed growth conditions in E and the depressed financial markets in R compound to generate large and persistent capital flows to U. Moreover, the exceptional growth conditions in R exacerbate rather than offset this pattern.[4]

After a series of preliminaries explaining the essence of our framework, we split the argument into three parts. In the first one, we study global equilibrium in a world with U and E countries only. This is the closest to the conventional analysis and has the dual role of showing the workings of our model and studying the equilibrium impact of a persistent decline in E's growth conditions, as experienced by Japan from the early 1990s and Continental Europe more recently. This decline raises capital flows from E to U and lowers global interest rates almost indefinitely. That is, the automatic rebalancing forces, regardless of the extent of home-bias, are tenuous in the absence of a reversal in the factors that led to the original imbalances, namely depressed growth conditions in E.

In the second part we study global equilibrium in a world with U and R countries only. This is the core of our model. We first show that if R's capacity to generate reliable financial assets crashes, global interest rates drop and capital flows from R to U permanently. Moreover, if growth potential in R is above that of the rest of the world, both effects are exacerbated. In particular, long run rates decline by more than short rates, and U can finance very significant current account deficits indefinitely. That is, if the initial asymmetry in financial development is not undone, the automatic rebalancing forces are even more tenuous than in the $U - E$ world. This part primarily captures the events following the Asian and Russian crises, as well as the fast growth and (favorably) high commodity prices experienced by much of the R region shortly afterwards. It also captures some of the elements following the crash of the Japanese bubble in the early 1990s.

We close this section by integrating the three regions. Aside from adding the effects of the previous two parts, we show that the shock in R has a larger (favorable) impact on U than on E. The reason is that the lower interest rates resulting from the asset markets collapse in R has a larger positive effect on asset values in the region with better growth prospects.

---

[4]Thus, the view that growth of US trading partners is on average similar to that of the US, so that differential growth cannot be a factor in explaining the large capital flows to the US, is misguided from our perspective. It matters a great deal who is growing faster and who is growing slower than the US. If those that compete with the US in asset production grow slower and those that demand assets grow faster, then both factors play in the same direction.

2.1 Preliminaries

2.1.1 A closed economy

Time evolves continuously. Infinitesimal agents (traders) are born at a rate θ per unit time and die at the same rate; population mass is constant and equal to one. At birth, agents receive a perishable endowment of $(1 - \delta)X_t$ which they save in its entirety until they die (exit). Agents consume all their accumulated resources at the time of death. The term $(1 - \delta)X_t$ should be interpreted as the share of national output that is not capitalizable.

The only saving vehicles are identical "trees" producing in aggregate a dividend of δX_t per unit time. Agents can save only in local trees.

By arbitrage, the instantaneous return from hoarding a unit of a tree, r_t, satisfies:

$$r_t V_t = \delta X_t + \dot{V}_t \tag{1}$$

where V_t is the value of the trees at time t. As is standard, the return on the tree equals the dividend price ratio $\delta X_t / V_t$ plus the capital gain $\dot{V}_t / V_t$.

Let W_t denote the savings accumulated by active agents at date t. Savings decrease with withdrawals (deaths), and increase with the endowment allocated to new generations and the return on accumulated savings:

$$\dot{W}_t = -\theta W_t + (1 - \delta)X_t + r_t W_t. \tag{2}$$

In equilibrium, savings must be equal to the value of the trees:

$$W_t = V_t. \tag{3}$$

Replacing (3) into (1), and the result into (2), yields a relation between savings and production:[5]

$$W_t = \frac{X_t}{\theta}. \tag{4}$$

Replacing this expression back into (1), using (3), we obtain an expression for the instantaneous equilibrium interest rate:

$$r_t = \frac{\dot{X}_t}{X_t} + \delta\theta, \tag{5}$$

Conditional on exogenous output X_t, the interest rate rises with growth because the latter lifts the rate of growth of financial wealth demand (W), and hence the expected capital gains from holding a tree; it rises with δ because this increases the share of income that is capitalizable and hence it raises the supply of assets; and it rises with θ because this lowers financial wealth demand and hence asset prices.

---

[5]By Walras' Law, noticing that θW_t corresponds to consumption, we can re-write this relation as a goods-market equilibrium condition:

$$\theta W_t = X_t.$$

We assume that the total endowment in the economy, X_t, grows at rate g. Hence r_t is given by r_{aut} where

$$r_{aut} = g + \delta\theta.$$

2.1.2 Discussion of our setup

This minimalist model has two ingredients that need further discussion: The parameter δ and the consumption function corresponding to our particular specification of preferences and demographics.

Let us start with the former. At any time t, let PV_t denote the present value of the economy's future output:

$$PV_t = \int_t^\infty X_s e^{-\int_t^s r_\tau d\tau} ds.$$

The parameter δ represents the share of PV_t that can be capitalized today and transformed into a tradable asset:

$$V_t = \delta PV_t.$$

Since the asset is traded, it belongs to the current generation.

In practice, δ captures many factors behind pledgeability of future revenues. At the most basic level, one can think of δ as the share of capital in production. But in reality only a fraction of this share can be committed to asset holders, as the government, managers, and other insiders can dilute and divert much of profits. It is for this reason that we refer to δ as an index of financial development, by which we mean an index of the extent to which property rights over earning are well defined and tradable in financial markets.

For given output and interest rate paths, as δ rises the share of tradeable PV_t rises and that of its complement, N_t:

$$N_t = (1 - \delta)PV_t$$

falls one for one.[6]

This takes us to the second key ingredient, our specification of preferences and demographics. For a change in δ to have any effect, it must have an impact on allocations. In particular, it must affect the total resources perceived by consumers (and hence by savers). If not, the economy is characterized by a situation akin to Ricardian equivalence: A rise in δ increases the supply of assets but it also raises the demand for assets one for one since non-capitalizable future income N_t falls by the same amount as V_t rises.

Thus, our choices are designed to provide the simplest model with non-Ricardian features. This is all that matters. Of course there is large number of alternatives to achieve the same goal, at the cost of additional complexity. For example, we could assume a perpetual youth model à la Blanchard (1985) with log preferences throughout. In fact, such model converges to ours if instead of giving agents a flow of labor income though life, we give them a lump sum at birth (see Appendix B). Moreover, our assumption of

---

[6]Of course, in reality limited financial development affects not only the distribution of revenues but also output and growth. Adding this dimension would exacerbate our results but make them less transparent.

consumption in the last day of life does the same for the aggregate as Blanchard's annuity market, in that the agent does not need to worry about longevity risk. Similarly, Weil (1987)'s model of population growth with infinitely lived agents collapses to ours if newly born agents receive the present value of their wages at birth. In both of these models, and their extensions to include ours, the consumption function of current agents takes the form (see Appendix B):

$$C_t = \theta(W_t + \beta N_t); \qquad \beta < 1.$$

The key point in these model as in ours is that current consumers do not have full rights over N_t while they do over V_t (and hence W_t).[7]

Finally, note that there is no need for an overlapping generations structure to have a role for asset supply. What is need is some demand for liquidity and that changing the supply of assets has allocational consequence. For example, Woodford (1990)'s model of infinitely lived agents with alternating liquidity demand also creates an environment where a change in the availability of financial assets affect allocations and interest rates.

2.1.3 A Small Open Economy

Let us now open the (small) economy, which faces a given world interest rate, r, such that:

Assumption 1 $g < r < g + \theta$

Definition 1 *(Trade Balance and Current Account): Let us denote the trade balance and current account at time t as TB_t and CA_t, respectively, with:*

$$TB_t \equiv X_t - \theta W_t$$
$$CA_t \equiv \dot{W}_t - \dot{V}_t$$

The definition of the trade balance is standard. The current account is also standard. It is the dual of the financial account and is defined as the increase in the economy's net asset demand.

To find the steady state of this economy, we integrate (1) forward and (2) backward:

$$V_t = \int_t^\infty \delta X_s e^{-r(s-t)} ds$$
$$W_t = W_0 e^{(r-\theta)t} + \int_0^t (1-\delta) X_s e^{(r-\theta)(t-s)}$$

Assumption 1 implies that asymptotically

$$\frac{V_t}{X_t} \underset{t\to\infty}{\to} \frac{\delta}{r-g} \tag{6}$$

$$\frac{W_t}{X_t} \underset{t\to\infty}{\to} \frac{1-\delta}{g+\theta-r} \tag{7}$$

---

[7]In Blanchard's model, the consumption function is $C_t = (p + \tilde{\theta})(W_t + H_t)$ where p is the probability of death and $\tilde{\theta}$ is the discount factor. H_t represents the aggregate value of the non-tradable asset and is strictly smaller than N_t as long as $p > 0$.

In Weil's model, and with the same notation, the consumption function is $C_t = \tilde{\theta}(W_t + H_t)$ and $H_t < N_t$ as long as the growth rate of population $n > 0$.
Figure 2: The Metzler diagram.

Equation (6) is just Gordon's formula. It shows that the asymptotic supply of assets, normalized by the size of the economy, is a decreasing function of r. Equation (7) describes the asymptotic demand for assets which, normalized by the size of the economy, is an increasing function of r. Figure 2 represents the equilibrium in a supply and demand diagram, a variation on the Metzler diagram. The supply curve and demand curve cross at $r = r_{aut}$.

If $r < r_{aut}$

$$\frac{\delta}{r - g} > \frac{1 - \delta}{g + \theta - r}$$

and domestic asset supply exceeds demand. Since along the balanced growth path $\dot{W}_t = gW_t$ and $\dot{V}_t = gV_t$, the above inequality implies that the small country runs an asymptotic current account deficit (financed by an asymptotic capital account surplus):

$$\frac{CA_t}{X_t} \underset{t \to \infty}{\to} g \left(\frac{1 - \delta}{g + \theta - r} - \frac{\delta}{r - g} \right) = -g \frac{(r_{aut} - r)}{(g + \theta - r)(r - g)}. \tag{8}$$

Note also that, asymptotically, the trade balance is in surplus: The lower rate of return on savings depresses wealth accumulation and, eventually, consumption

$$\frac{TB_t}{X_t} \underset{t \to \infty}{\to} \frac{r_{aut} - r}{g + \theta - r} \tag{9}$$

Importantly, however, this asymptotic trade surplus is *not* enough to service the accumulated net external liabilities of the country, which is why the current account remains in deficit forever.

Conversely, note that when $r > r_{aut}$, (8) and (9) still hold, but now the economy runs an asymptotic current account surplus.

We can prove a stronger result that will be useful later on.

10

Lemma 1 *Consider a path for the interest rate $\{r_t\}_{t \geq 0}$ such that $\lim_{t \to \infty} r_t = r$ with $g < r < g + \theta$. Then*

$$\frac{V_t}{X_t} \underset{t \to \infty}{\to} \frac{\delta}{r - g}, \qquad \frac{W_t}{X_t} \underset{t \to \infty}{\to} \frac{1 - \delta}{g + \theta - r}$$

$$\frac{CA_t}{X_t} \underset{t \to \infty}{\to} -g \frac{(r_{aut} - r)}{(g + \theta - r)(r - g)}, \qquad \frac{TB_t}{X_t} \underset{t \to \infty}{\to} \frac{r_{aut} - r}{g + \theta - r}$$

Proof. See the appendix. ∎

2.2 A World with Symmetric (and Developed) Financial Markets (A $U - E$ World)

Let us now study global equilibrium with two large regions, $i = \{U, E\}$. Each of them is described by the same setup as in the closed economy, with an instantaneous return from hoarding a unit of either tree, r_t, which is common across both regions and satisfies:

$$r_t V_t^i = \delta X_t^i + \dot{V}_t^i \tag{10}$$

where V_t^i is the value of country i's tree at time t. Let W_t^i denote the savings accumulated by active agents in country i at date t:

$$\dot{W}_t^i = -\theta W_t^i + (1 - \delta) X_t^i + r_t W_t^i. \tag{11}$$

Adding (10) and (11) across both regions, yields:

$$r_t V_t = \delta X_t + \dot{V}_t \tag{12}$$

$$\dot{W}_t = -\theta W_t + (1 - \delta) X_t + r_t W_t \tag{13}$$

with

$$W_t = W_t^U + W_t^E, \qquad V_t = V_t^U + V_t^E, \qquad X_t = X_t^U + X_t^E.$$

From now on, the solution for global equilibrium proceeds exactly as in the closed economy above, with

$$\theta W_t = X_t. \tag{14}$$

and

$$r_t = \frac{\dot{X}_t}{X_t} + \delta \theta. \tag{15}$$

Let us now specify the initial conditions and follow with our first shock.

Assumption 2 *(Initial Conditions): The world is initially symmetric, with equal levels of X_t^i and a constant rate of growth, common to both countries, g. There are no (net) capital flows across the economies and $W_t^U = V_t^U = V_t^E = W_t^E$.*

Suppose now that, unexpectedly, at $t = 0$, the rate of growth of E drops permanently to

$$g^E < g.$$

11

Lemma 2 *(Continuity): At impact, r absorbs the shock while V and W remain unchanged.*

Proof. At any point in time, it must be true that

$$W_t = \frac{X_t}{\theta}$$

It follows that W_t does not jump at $t = 0 : W_{0-} = W_{0+} = X_0/\theta$. Since $W_t = V_t$ must hold at all times, we conclude that V_t does not jump either: $V_{0-} = V_{0+} = X_0/\theta$. But for this absence of a decline in V at impact to be consistent with the asset pricing equation, the growth slowdown in E must be offset by a drop in r:

$$r_{0+} = \frac{g + g^E}{2} + \delta\theta < r_{0-} = g + \delta\theta$$

that reflects a decline in world output growth.[8] ∎

While global wealth and capitalization values do not change at impact, the allocation of these across economies does. On one hand, it stands to reason that the lower growth in X_t^E implies that V_0^U/V_0^E must rise since both dividend streams are discounted at the common global interest rate. On the other, whether W_0^U/W_0^E rises or not depends on the agents' initial portfolio allocations. However, as long as there is some home bias in these portfolios, W_0^U/W_0^E rises as well. Because the conventional view has taken the well established fact of home bias as a key force bringing about rebalancing of portfolios, we shall assume it as well, as this isolates the contribution of our mechanisms more starkly. Moreover, for clarity, in the main propositions we assume an extreme form of home bias, but then extend the simulations and figures to other cases.

Assumption 3 *(Home Bias). Agents first satisfy their saving needs with local assets and only hold foreign assets once they run out of local assets.*

This assumption implies that, at impact, local wealths' changes match the changes in the value of local trees one-for-one:

$$W_{0+}^E - \frac{W_0}{2} = V_{0+}^E - \frac{V_0}{2}$$
$$W_{0+}^U - \frac{W_0}{2} = V_{0+}^U - \frac{V_0}{2}$$

These changes in wealth have a direct impact on consumption, which are reflected immediately in the trade balance and current account.

Before describing these effects, let us digress momentarily. At times, it will be convenient for exposition to note that the current account can also be written as the sum of trade balance and net income from global holdings:

---

[8] According to the World Development Indicators, average output growth for U, E and R was 3.41% in the 1980s, 2.77% in the 1990s and 2.75% since 2000.

Lemma 3 *(Alternative Formulation of the Current Account)*

$$CA_t^i = X_t^i - \theta W_t^i + r_t(\alpha_t^{i,j} V_t^j - \alpha_t^{j,i} V_t^i)$$
$$= TB_t^i + r_t(\alpha_t^{i,j} V_t^j - \alpha_t^{j,i} V_t^i)$$

where $i \neq j$, $\alpha_t^{i,j}$ is the share of country j's trees held by agents in country i, $\alpha_t^{j,i}$ is the share of country i's trees held by agents in country j.

Proof. See the appendix. ∎

Note that our current account definition excludes, as does national accounts, unexpected valuation effects (unexpected capital gains and losses from international positions). This is not a relevant issue for now since the only surprise takes place at date 0, when agents are not holding international assets. We shall return to this issue when relevant.

Also note that since $CA_t^E + CA_t^U = 0$, we only need to describe one of the current accounts to characterize both. Henceforth, we shall describe the behavior of CA_t^U, with the understanding that this concept describes features of the global equilibrium rather than U-specific features.

Finally, without any substantive implication (see the Appendix for the general case), we make an assumption to narrow the asymptotic cases we need to analyze:

Assumption 4 *(Bounded Growth Decline):* $(g - g^E) < (1 - \delta)\theta$.

Proposition 1 *(Persistent Current Account Deficits in U):* *Under assumptions 1 to 4, an unexpected and persistent decline in E's rate of growth from g to $g^E < g$, turns CA_t^U into a deficit at impact and remains in deficit in the long run (although vanishing asymptotically relative to X_t^U).*

Proof. At impact, we have

$$W_{0+}^U = V_{0+}^U$$

$$CA_0^U = TB_0^U = X_0^U - \theta V_{0+}^U < 0$$

For $t > 0$, using $\theta W_t = X_t$ and $\theta V_t = X_t$ we have

$$CA_t^U = \dot{W}_t^U - \dot{V}_t^U = \dot{V}_t^E - \dot{W}_t^E$$

From equation (15) and $g > g^E$, $\lim_{t\to\infty} r_t = r_{aut}^U$. Lemma 1 shows that

$$\frac{V_t^E}{X_t^E} \xrightarrow[t\to\infty]{} \frac{\delta}{r_{aut}^U - g^E}$$
$$\frac{W_t^E}{X_t^E} \xrightarrow[t\to\infty]{} \frac{(1-\delta)}{g^E + \theta - r_{aut}^U}$$

and

$$\frac{CA_t^U}{X_t^E} = -\frac{CA_t^E}{X_t^E} \xrightarrow[t\to\infty]{} -\frac{g^E(r_{aut}^U - r_{aut}^E)}{(g^E + \theta - r_{aut}^U)(r_{aut}^U - g^E)} < 0.$$

13

Finally, it follows immediately from $g > g^E$ that CA_t^U / X_t^U vanishes asymptotically. ∎

The impact effect of a decline in E's rate of growth is a decline in the value of E's assets which drags down E's wealth one for one given the extreme home bias assumption. This leads to an immediate drop in E's consumption which is not matched by a drop in E's current income. Thus E's trade balance, which is equal to the current account in the symmetric initial equilibrium, goes into surplus. In equilibrium, U has to absorb this surplus by running a trade deficit. The latter is achieved by an increase in U's consumption, which results from an increase in U's wealth following the appreciation of U's assets. This appreciation does not stem from any increase in U's growth prospects, but from the fall in interest rates brought about by E's slowdown.

Suddenly U's assets look relatively more attractive, and hence a share of E's saving begins to flow to these assets. Over time, the return on these assets raises E's wealth and consumption (relative to output), eventually overturning the initial trade surplus, and hence U' s trade deficit.

However, U's eventual trade surpluses are never enough to service the accumulated net-foreign liabilities in full, and hence U's current account remains in deficit forever. The counterpart of this persistent deficit is a sustained accumulation of U's assets by E. This accumulation is very fast early on, as the relative importance of U assets in E's portfolio rises until it converges (asymptotically) to:

$$\frac{g - g^E}{((1-\delta)\theta - (g - g^E))\left((g - g^E) + \delta\theta\right)} > 0.$$

Thus, in the limit, E continuously accumulates U's assets at a rate g^E.

Of course, this does not mean that our model violates the intertemporal approach to the current account. Integrating forward the equation:

$$\dot{W}_t^U - \dot{V}_t^U = X_t^U - \theta W_t^U + r_t(W_t^U - V_t^U)$$

we find the usual expression:

$$\begin{aligned} W_t^U - V_t^U &= -\int_t^\infty \left(X_s^U - \theta W_s^U\right) e^{-\int_t^s r_u du} ds \\ &= -\int_t^\infty TB_s^U e^{-\int_t^s r_u du} ds. \end{aligned}$$

In particular

$$0 = W_{0+}^U - V_{0+}^U = -\int_0^\infty TB_t^U e^{-\int_0^t r_s ds} dt.$$

Since the initial net asset position is balanced in our basic scenario, the net present value of trade balance surpluses is zero. The trade balance TB_t^U is initially in deficit and eventually turns into surplus since:

$$\frac{TB_t^U}{X_t^E} = -\frac{TB_t^E}{X_t^E} \underset{t \to \infty}{\longrightarrow} \frac{g - g^E}{g^E + \theta - r_{aut}^U} > 0.$$

Importantly, however, increased net interest payments to E due to U's accumulation of net foreign liabilities exceed the trade balance surpluses and generate a chronic current account deficit in U.
Figure 3: A Collapse in g^E

We can understand the asymptotic result in the proposition with reference to the simple small open economy in Section 2.1, and its Figure 2. First, since in the long run U dominates the global economy, the equilibrium interest rate converges to the Autarky interest rate for U:

$$r_\infty = r_{aut}^U = g + \delta\theta.$$

Thus the gap between W_t^U/X_t^U and V_t^U/X_t^U is asymptotically vanishing. However, note that the limit interest rate exceeds the new Autarky rate in E:

$$r_\infty = g + \delta\theta > g^E + \delta\theta = r_{aut}^E.$$

Thus the asymptotic gap between W_t^E/X_t^E and V_t^E/X_t^E is strictly positive. Moreover, by global equilibrium this means that the asymptotic gap between W_t^U/X_t^E and V_t^U/X_t^E is strictly *negative.*

Let us now turn to a characterization of the entire path. Figure 3 portrays an example of the impact of a growth slowdown for parameters calibrated to match some key aspects of the data.[9] Our only goal here is to consolidate the insights from the proposition and to argue that the effects we describe are quantitatively significant. We do not attempt to match the exact paths in the data, as that would require additional smoothing mechanisms, such as gradual globalization, and other adjustment costs. Absent these, adjustments are too large at impact and too fast. Still, note that even in this frictionless environment, adjustments are gradual and capital flows remain large many years after the shock. Also note that the cumulative results, which are more robust to the absence of frictions, are large

---

[9]See the appendix for a discussion of the calibration. The drop in E's growth rate is about one percent.

15

Panel A of Figure 3 shows that U's current account/GDP exhibits large initial deficits of 17 percent of output, which converge to zero only gradually. Panel B reports U's net external position. The growth shock lowers V^E relative to V^U. Since in order to match Figure 1(c), we calibrated U's assets share in initial global portfolio to 5% (rather than the 0% in the proposition), U suffers a small initial valuation loss.[10] More centrally, the large initial current account deficits worsen rapidly U's net foreign asset position from zero to -75 percent in 15 years. Eventually, the net foreign asset position converges to zero (relative to domestic output), but panel B illustrates that this convergence is slow, and in fact comes entirely from the denominator (output growth) since U never runs a current account surplus. Given our parameter values, the initial real interest rate equals 6 percent. Panel C shows that it drops by about 60 basis points at impact, then climbs back very slowly to pre-shock levels. Finally, the last panel shows the share of U's assets in E's wealth, under the assumption that U maintains its initial holdings. This portfolio share increases rapidly from 5 percent to 25 percent, and asymptotes to 34 percent.

The model is thus able to generate simultaneously large and long lasting current account deficits in U (Fact 1); a decline in real interest rates (Fact 2) and an increase in U's share in the global portfolio (Fact 3).

Up to now, differential growth limited the aggregate ability to create valuable assets in E relative to U. But there are other factors that create comparative advantage in asset creation, such as institutional differences, ranging from corporate governance to transparency of the financial system and policymaking. We turn to this analysis next, which is at the core of our explanation for recent global imbalances.

2.3 A World with Asymmetric Financial Markets (a $U-R$ World)

Let us now turn to the interaction between U and R. For clarity, we shall remove E from the analysis for now. The key element of this part of the model is that R is able to grow and generate income for savers but is limited in its ability to generate sound financial assets for these savers.

In this section we develop our argument in two steps: First, at date 0 we let R's δ drop from δ to $\delta^R < \delta$, in an environment where R and U are growing at the same rate g. Second, we repeat the experiment but now in an environment where R is growing faster than U, $g^R > g$.

How should we interpret a drop in δ^R? In general, as the realization that local financial instruments are less sound than they were once perceived to be. This could result from, *inter alia*, a crash in a bubble; the realization that corporate governance is less benign than once thought; a significant loss of informed and intermediation capital; the sudden perception —justified or not— of "crony capitalism"; a sharp decline in property rights protection, and so on. All of these factors -and more- were mentioned in the events surrounding the Asian/Russian crises (e.g. Fischer (1998)).

The formulae are very similar to that in the $U-E$ model, but there are some differences that need to be highlighted. Let quantities without superscript denote world aggregates (now made of U and R, rather

---

[10]That is, the initial jump at $t = 0^+$ reflects the unexpected valuation effect from U's holdings of E's asset. Recall that our convention, similar to NIPA or BoP accounting, excludes these valuation effects from the current account.

than U and E), then:

$$r_t V_t^R \;=\; \delta^R X_t^R + \dot{V}_t^R$$

and

$$r_t V_t = \delta X_t - \left(1 - x_t^U\right)(\delta - \delta^R) X_t + \dot{V}_t$$

with $x_t^U \equiv X_t^U / X_t$. Similarly, we have that:

$$\dot{W}_t^R = (1 - \delta^R) X_t^R + (r_t - \theta) W_t^R$$

and

$$\dot{W}_t = \left[1 - \delta + (\delta - \delta^R)(1 - x_t^U)\right] X_t + (r_t - \theta) W_t$$

Finally, using the equilibrium conditions $W = V = X/\theta$, and the arbitrage equation for V, we can solve for the equilibrium interest rate as before:

$$
\begin{align}
r_t &= x_t^U(g + \delta\theta) + (1 - x_t^U)(g + \delta^R\theta) \tag{16} \\
&= r_{aut}^U - (1 - x_t^U)(\delta - \delta^R)\theta. \tag{17}
\end{align}
$$

Proposition 2 (*Crash in R's Financial Markets with Symmetric Growth*): *Assume R and U grow at the same rate g. Under Assumption 3, if δ drops in R to $\delta^R < \delta$, then the current account of U turns into a deficit at impact and remains in deficit thereafter, with CA_t^U / X_t^U converging to a strictly negative constant. The interest rate falls permanently below r_{aut}^U.*

Proof. Note first that since both regions are growing at the same rate, $x_t^U = x_0^U$ for all $t > 0$, and the interest rate remains constant after dropping at date 0:

$$r_t = r^+ = r_{aut}^U - (1 - x_0^U)(\delta - \delta^R)\theta < r_{aut}^U. \tag{18}$$

Next, because the interest rate is constant, the values of the trees change immediately to their new balanced growth path:

$$V_t^R = \frac{\delta^R X_t^R}{r^+ - g}, \qquad V_t^U = \frac{\delta X_t^U}{r^+ - g}.$$

Let us now describe the balanced growth path and then return to describe transitory dynamics. In the balanced growth path, we know from Lemma 1 that

$$W_t^R = \frac{(1 - \delta^R) X_t^R}{\theta + g - r^+} \qquad W_t^U = \frac{(1 - \delta) X_t^U}{\theta + g - r^+}$$

and

$$\frac{CA_t^U}{X_t^U} = -g \frac{r_{aut}^U - r^+}{(g + \theta - r^+)(r^+ - g)} < 0.$$

For transitory dynamics, define $w_t^R = W_t^R / X_t^R$ so that

$$\dot{w}_t^R = (r^+ - g - \theta) w_t^R + (1 - \delta^R).$$

17

with a balanced growth equilibrium value of $(1 - \delta^R)/(\theta + g - r^+)$.

From home-bias Assumption 3 we have that

$$w_{0+}^R = \frac{V_{0+}^R}{X_0^R} < \frac{1 - \delta^R}{\theta + g - r^+}$$

since $r^+ < r_{aut}^U$. That is, w_t^R is below its balanced growth path at $t = 0^+$.

Since $r^+ < r_{aut}^U < g + \theta$, we must have $\dot{w}_t^R > 0$ when w_t^R is below its steady state, or equivalently:

$$\dot{W}_t^R > g W_t^R$$

Thus we also have that U's current account $CA_t^U = \dot{V}_t^R - \dot{W}_t^R$ is in deficit – in fact, a larger deficit– before converging to its new balanced growth path. ∎

That is, now even if both regions have similar rates of growth, U runs a permanent current account deficit. The latter is the counterpart of the increasing flow of resources from R-savers, who have few reliable local assets to store value and hence must resort to U-assets. In balanced growth, R-savings grow at the rate of growth of income. If R-savings are below (output-detrended) steady state, then the rate of accumulation exceeds the rate of growth of the economy and capital flows toward U grow at a fast rate (faster than g).

The collapse in δ^R decreases the global supply of assets by reducing the share of R's income that can be capitalized. As before, the shock is entirely absorbed via a decline in world interest rates, reflecting a decline in the global dividend rate from δ to $\delta - (1 - x_0)(\delta - \delta^R)$. While global wealth and capitalization do not change at impact, the allocation of wealth and assets across countries does. The collapse in δ^R implies that V_0^U/V_0^R must rise as an unchanged stream of U's dividends is now discounted at a lower interest rate. Correspondingly, under our home bias assumption, the ratio W_0^U/W_0^R must also rise.[11]

Again, we can resort to the analysis of a small open economy in Section 2.1, and its Figure 2, to understand the asymptotic result. For this, note that the equilibrium interest rate falls to a level in between the two ex-post Autarky rates:

$$r_{aut}^U = g + \delta\theta > r^+ = g + \delta\theta - (1 - x_0^U)(\delta - \delta^R)\theta > g + \delta^R\theta = r_{aut}^R$$

Thus the gap between W_t^U/X_t^U and V_t^U/X_t^U is negative and *non*-vanishing (see Lemma 1). Or, from the other region's perspective, the gap between W_t^R/X_t^R and V_t^R/X_t^R is positive and non-vanishing. Figure 4 presents the asymptotic result. Starting from a symmetric equilibrium at A and A^* with a world interest rate r_{aut}^U, the decline in δ^R shifts the V^R/X^R curve to the left (decline in asset supply) and the W^R/X^R curve to the right (increase in asset demand). The world interest rate declines just enough so that the net foreign assets in U ($NA^U \equiv W^U - V^U < 0$) and the net foreign assets in R ($NA^R \equiv W^R - V^R > 0$) sum to zero.

---

[11]It is easy to show that if δ^R crashes to zero, then a bubble must arise in U-trees. While that drop in δ^R is extreme, it captures the flavor of the behavior of U's asset markets in recent years. In the less extreme version we have highlighted, we still capture this flavor through the rise in the value of U's fundamentals following the decline in equilibrium interest rates.
Figure 4: The Metzler diagram for a permanent drop in δ^R.

Figure 5 characterizes the entire path following a collapse of δ^R calibrated so that R's asset prices drop by 50% on impact (see the appendix for a discussion). Again, our objective is not to match the precise trajectory of the US current account following the Asian crisis, but to argue that the effects we describe are quantitatively significant. Panel A of Figure 5 shows that U's current accounts exhibit large initial deficits of 20 percent. The current account remains negative and asymptotes at -2.8 percent of output. As in the $U - E$ case, the large initial current account deficits worsen rapidly the net foreign asset position from -6 percent at impact to -95 percent (panel B). The real interest rate drops by slightly more than 50 basis points and remains permanently lower. Finally, U's share in R's portfolio increases gradually from 11 percent (immediately after the shock) to 55 percent.[12]

Once again, the model is able to generate, simultaneously, large and long lasting current account deficits in U (Fact 1); a decline in real interest rates (Fact 2) and an increase in the share of U's assets in global portfolios (Fact 3).

Importantly, now CA_t^U / X_t^U does not vanish asymptotically as it converges to:

$$\frac{CA_t^U}{X_t^U} = -g \frac{(\delta - \delta^R)(1 - x_0^U)\theta}{(\theta + g - r^+)(r^+ - g)} < 0.$$

The reason is that excess savings needs in R grow with R's output, which grows in tandem with U's output.

Note also that the size of the permanent current account deficit in U (relative to output) is increasing in the relative size of R (equal to $(1 - x_0^U)$). This observation hints at an important additional source of large and persistent deficits in U. In practice, R's rate of growth exceeds that of U, and hence the relative importance of this source of funding of U-deficits rises over time — both, because of differential growth and because many R countries are gradually globalizing.

Let us now turn to our second experiment and explore the effect of a crash in δ^R that takes place in an

---

[12]The initial jump from 5 to 11 percent reflects the drop in R's wealth and jump in V^U at $t = 0^+$.
Figure 5: A Collapse in δ^R

environment where:

$$g^R > g.$$

The instantaneous interest rate in this case is:

$$r_t = x_t^U \left(g + \delta\theta\right) + (1 - x_t^U)(g^R + \delta^R\theta). \tag{19}$$

Let us assume that the additional growth in R is not enough to offset the effect of a lower δ^R on interest rates:

Assumption 5 *(Lower ex-post autarky rate in R)* $r_{aut}^R = g^R + \theta\delta^R < r_{aut}^U - \theta(1 - x_0^U)(\delta - \delta^R) < r_{aut}^U$

Proposition 3 *(Crash in R's Financial Markets with High Growth in R) Suppose that Assumptions 3 and 5 hold, but that $g^R > g$. If at date 0 δ drops to δ^R in R, then:*

$$r_{aut}^U = r_{0^-} > r_{0^+} > r_\infty = r_{aut}^R$$

and the asymptotic current account deficit in U relative to its output is larger when $g^R > g$ than when $g^R = g$:

$$\lim_{\substack{t \to \infty \\ g^R > g}} \frac{CA_t^U}{X_t^U} < \lim_{\substack{t \to \infty \\ g^R = g}} \frac{CA_t^U}{X_t^U} < 0$$

Proof. See the appendix. ∎

The result in this proposition is intuitive given the previous proposition: As R's growth rises, so does its demand for financial assets. Since this rise is not matched by an increase in R's ability to generate

20

financial assets, these assets must be found in U and interest rates drop as the price of U-assets rise. The corresponding increase in capital flows finances the larger current account deficit in U. Long run interest rates fall more than the short term interest rates because the relative importance of the country with excess demand for assets, R, rises over time.

As before, let us now describe the asymptotic result in terms of Figure 2, from Section 2.1. First, since in the long run R dominates the global economy when $g^R > g$, the equilibrium interest rate converges to the Autarky interest rate for R:

$$r_\infty = r_{aut}^R = g^R + \delta^R \theta.$$

Thus, relative to X_t^R, the gap between W_t^R and V_t^R is vanishing, and so is that between W_t^U and V_t^U.

However, note that this limit interest rate is below the Autarky rate in U:

$$r_\infty = g^R + \delta^R \theta < g + \delta\theta = r_{aut}^U.$$

Thus, relative to X_t^U, the gap between W_t^U and V_t^U is negative and *not* vanishing. Moreover, since

$$r_\infty < r^+ < r_{aut}^U,$$

that gap is larger when $g^R > g$ than when $g^R = g$.

2.4 The Three Regions World ($U - E - R$)

In this section, we consider a $U - E - R$ environment. Much of this world is simply the sum of the two sub-worlds described above, but there is one additional insight: If the crash in δ^R takes place when $g^U > g^E$, then the asset appreciation in U is (much) larger than that in E, and the bulk of the capital flows from R are directed to U rather than to E.

Since the dynamic equations follow directly from those discussed above, we relegate them to the appendix and state the main proposition directly, after making an assumption on the parameter region under consideration:

Assumption 6 $r_{aut}^R \equiv g^R + \delta^R \theta < r_{aut}^U \equiv g + \delta\theta$, $r_{aut}^R < g^E + \theta$, $g^E < g$.

Proposition 4 (*Disproportionate Flows toward U*) *If Assumption 6 holds, then a crash in δ^R leads to an increase in V^U/V^E and a "disproportionate" (to relative output) allocation of R's capital outflows to U over E. Asymptotically*

$$\frac{\frac{\delta^R}{V_t^U}\frac{\partial V_t^U}{\partial \delta^R}}{\frac{\delta^R}{V_t^E}\frac{\partial V_t^E}{\partial \delta^R}} = \frac{r_\infty - g^E}{r_\infty - g} = 1 + \frac{g - g^E}{r_\infty - g} > 1.$$

Proof. See the appendix. ∎

In words, the reduction in world interest rates stemming from the crash in δ^R has a larger impact on U-assets since these are more leveraged than E-assets when $g > g^E$. This difference can be quite large. For
21

Figure 6: A Collapse in g^E followed by a collapse in δ^R in the U-E-R model

a decline in δ^R calibrated so that V^R collapses by 50 percent on impact, with $g = g^R$ and a 1.1 percent growth differential $g - g^E$, the ratio of asset price elasticities equals 1.43.

Figure 6 traces the entire path in the case where $g = g^R$. We start the economy in a symmetric equilibrium ($g^i = g$ and $\delta^i = \delta$), with $x_0^U = x_0^E = 0.425$ and $x_0^R = 0.15$. We then reduce E's growth at $t = 0$. This reduces world interest rates to 5.5 % and increases asset values in R and U as both regions receive capital inflows (panel D). Then, at $t = 5$, we decrease δ^R. Panel D illustrates that the collapse in δ^R and V^R disproportionately affects V^U relative to V^E: V^U increases by 12 percent at $t = 5$, compared to 8 percent for V^E. This results in much larger current account deficits in U relative to E and an additional build-up in net liabilities in U (panel A).

3   Investment Slumps and Foreign Direct Investment

Let us now add an investment margin to the $U - R$ model and a reason for foreign direct investment (FDI). We capture the former with the emergence of options to plant new trees over time, and the latter with U's ability to convert new R trees into δ (rather than δ^R) trees.[13] These additions enrich the framework along two important dimensions in matching the facts: First, the collapse in δ^R can lead to an investment slump in R which exacerbates our results in the previous section. Second, the intermediation rents from FDI reduce the trade surpluses that U needs to generate to repay for its persistent early deficits.[14]

---

[13]Note that in a three regions version of the model E also could convert R trees. Although in this case, a good question is which rate of growth would the output of those trees have.

[14]The view here is not unrelated to that in Despres, Kindleberger and Salant (1966) and Kindleberger (1965), who during the Bretton Woods era argued that the US had a unique role as a provider of international currency liquidity. More recently,

3.1 An Investment Margin and Slump

Let us split aggregate output in each region into the number of trees, N, and the output per tree, Z:

$$X_t^i = N_t^i Z_t^i$$

At each point in time, $g^n N_t^i$ options to plant new trees arise. At the same time, the output of each planted tree grows at the rate g^z. Planting the $g^n N_t^i$ new trees consumes resources I_t^i:

$$I_t^i = \kappa X_t^i.$$

Let us assume first that κ is low enough so that all investment options are exercised (see below), and hence aggregate output grows at rate g, with (equal for both regions):

$$g = g^n + g^z.$$

Suppose for now that δ^i is specific to the region where the tree is planted, not to who planted it. Then

$$r_t V_t^i = \delta^i X_t^i + \dot{V}_t^i - g^n V_t^i \tag{20}$$

where V_t^i represents the value of all (new and old) trees planted at time t in region i, and $\dot{V}_t^i - g^n V_t^i$ represents the expected capital gains from those trees.

The options to invest are allocated to all those alive at time t within each region, who immediately exercise them by investing I_t^i.[15] Thus,

$$\dot{W}_t^i = (r_t - \theta)W_t^i + (1 - \delta^i)X_t^i + g^n V_t^i - I_t^i.$$

As usual, aggregating across both regions to find the equilibrium interest rate, yields:

$$r_t V_t = \delta X_t - (\delta - \delta^R)X_t^R + \dot{V}_t - g^n V_t \tag{21}$$

$$\dot{W}_t = (r_t - \theta)W_t + (1 - \delta)X_t + (\delta - \delta^R)X_t^R + g^n V_t - I_t \tag{22}$$

Gourinchas and Rey (forthcoming 2006) have documented that the total return on US gross assets (mostly equity and FDI) consistently exceeded the total return on gross liabilities (mostly safe instruments) by an average of 3.32 percent per year since 1973. Of course part of this excess return is due to the risk-premium differential associated to the leveraged nature of US investments. Our analysis omits this risk dimension and focus on the "intermediation" rent obtained by the US.

Everything suggests that this "intermediation" role of the US has only grown in importance as total gross capital flows to/from the US have risen from \$222 billion in 1990 to \$2.3 trillion in 2004 (see BEA, US International Transactions Accounts, Table 1). See also Lane and Milesi-Ferretti (forthcoming 2006) for a systematic analysis of cross border flows and positions for a large sample of countries.

[15]Note that the share of options that are allocated to existing owners of trees are subsumed within the Z component. In fact, we can reinterpret the model in Section 2 as an investment model where all the options are allocated to the owners of existing trees. The only reason we modified the allocation of options in this section is to spread the excess returns from FDI over time in a more realistic manner (otherwise the entire capitalized excess returns accrues to the first generation in U).

so that:

$$W_t = V_t = (1 - \kappa)\frac{X_t}{\theta}.$$

and

$$r = g^z + \frac{\theta}{1 - \kappa}(\delta - (\delta - \delta^R)\, x^R) < r_{aut}^U = g^z + \frac{\theta\delta}{1 - \kappa}, \tag{23}$$

which amounts to the same model as in the previous section, with the exceptions that only the rate of growth of output per-tree enters, and that the investment cost reduces wealth accumulation and hence raises the interest rate (since it lowers the price of trees).

Let us now assume that the drop in δ^R is large enough that investment is not privately profitable in R (κ is large relative to $g^n V_t^R / X_t^R$). This immediately delivers an (extreme) investment slump in R.[16] Moreover, the equations for R change to:

$$g^R = g^z < g.$$

$$r_t V_t^R = \delta^R X_t^R + \dot{V}_t^R \tag{24}$$

$$\dot{W}_t^R = (r_t - \theta)W_t^R + (1 - \delta^R)X_t^R. \tag{25}$$

Solving for global equilibrium, yields:

$$V_t = W_t = (1 - \kappa x_t^U)\frac{X_t}{\theta}.$$

Note that now at the time of the crash in δ^R there is an *increase* in the value of global assets equal to:

$$\Delta V_0 = \kappa\frac{X_t^R}{\theta} > 0.$$

The mechanism behind this increase in asset value —made of a milder decline in asset values in R and a sharper appreciation in U— is a further drop in interest rates at impact following the investment collapse in R.[17] Moreover, the latter exacerbates the initial current and trade deficit in U.

The following proposition summarizes these results more precisely and is proved in the appendix. It compares two situations when $g^n V_t^R / X_t^R < \kappa$. In situation 1, R agents make the optimal decision not to invest. In situation 2, which is intended only to serve as a benchmark, R agents are forced to exercise their investment options.

Proposition 5 *(Investment slump) At impact, the drop in interest rate is larger under situation* 1 *than under situation* 2*. Also, the initial current account and trade balance deficits in U are larger in situation* 1 *than in situation* 2*.*

---

[16] See Caballero and Krishnamurthy (2006) for a more detailed emerging markets model where the collapse in the "bubble" component of (something like) δ^R leads to an investment slowdown in R.

[17] Note that in the long run the interest rate converges to r_{aut} since now U is growing faster than R. However this long run rise is not enough to offset the sharp decline in interest rates in the short (and medium) run.

3.2 An Intermediation Margin: Foreign Direct Investment

Let us now assume that R residents can sell the options to the news trees to U residents at price, P:

$$P_t = \kappa_P X_t^{Rn}.$$

where X_t^{Rn} denotes the output from the trees sold to U. We think of this price as the result of some bargaining process but its particular value is not central for our substantive message as long as it leaves some surplus to U.

There are gains from trade: If U residents plant the new R trees, the share of output from the new trees that can be capitalized rises from δ^R to δ. Suppose that P_t is such that all new R trees are planted by U residents. In fact, the following assumption ensures that U investors and R sellers gain from foreign direct investment along the entire path.

Assumption 7 (Asymptotic Bilateral Private Gains from FDI) *Let κ_P and $(\delta - \delta^R)$ be such that:*

$$g^n \frac{\delta}{r_{aut} - g^z} > \kappa + \kappa_P > g^n \frac{\delta^R}{r_{aut} - g^z}$$

Proposition 6 *If Assumption 7 holds, then U runs an asymptotic trade deficit financed by its intermediation rents.*

Proof. Let us assume that enough time has passed so that the output of the old R trees is negligible relative to the total output produced by trees planted in R by U. We have:

$$(r_t + g^n)V_t^i = \delta X_t^i + \dot{V}_t^i$$

$$(r_t + g^n)V_t = \delta X_t + \dot{V}_t$$

$$\dot{W}_t^U = (r_t - \theta)W_t^U + (1 - \delta)X_t^U + g^n V_t - (I_t^U + I_t^R) - P_t.$$

$$\dot{W}_t^R = (r_t - \theta)W_t^R + (1 - \delta)X_t^R + P_t.$$

$$\dot{W}_t = (r_t - \theta)W_t + (1 - \delta)X_t + g^n V_t - I_t \tag{26}$$

so that:

$$W_t = V_t = (1 - \kappa)\frac{X_t}{\theta}.$$

and

$$r = r_{aut} = g^z + \frac{\delta\theta}{1 - \kappa} \tag{27}$$

It follows from derivations analogous to those in previous sections that:

$$\frac{W_t^U}{X_t^U} \rightarrow \frac{(1 - \delta - \kappa) + g^n \frac{\delta}{r_{aut} - g^z} + g^n \frac{\delta x^R/x^U}{r_{aut} - g^z} - (\kappa + \kappa_P) x^R/x^U}{\theta + g - r_{aut}}$$

and since $TB_t^U = -\theta W_t^U - I_t^U + X_t^U$, we have that:

Figure 7: A Collapse in δ^R with and without FDI

$$
\begin{aligned}
\frac{TB_t^U}{X_t^U} &\to -\theta \frac{(1-\delta-\kappa) + g^n \frac{\delta}{r_{aut}-g^z} + g^n \frac{\delta x^R/x^U}{r_{aut}-g^z} - (\kappa+\kappa_P)\, x^R/x^U}{\theta + g - r^{U,aut}} + (1-\kappa) \\
&= -\theta \frac{x^R}{x^U} \frac{g^n \frac{\delta}{r_{aut}-g^z} - (\kappa+\kappa_P)}{\theta + g - r_{aut}} < 0.
\end{aligned}
$$

That is, the trade balance is in deficit in the long run as long as there is an intermediation rent, which is ensured by Assumption 7. ∎

Does this mean that the intertemporal approach of the current account has been violated? Certainly not. It simply means that the intermediation rents rather than future trade surpluses pay for the initial (and now permanent) trade deficits. Alternatively, one could account for these intermediation services as "non-traditional" net exports and imports for U and R, respectively. In which case, we have:

$$
\widehat{TB}_t^U = TB_t^U + g^n V_t^R - (\kappa + \kappa_P) X_t^R
$$

and, assuming $r_{aut} > g$ so the integral converges, it follows that:

$$
W_t^U - V_t^U = -\int_t^{+\infty} \widehat{TB}_s^U e^{-\int_t^s r_u\,du}\,ds
$$

Figure 7 reports the path of U's trade balance following a collapse in δ^R.[18] We consider three cases: first, when κ_P is sufficiently high that no FDI takes place. Second, when all the rents asymptotically go

---

[18]We calibrate the decline in δ^R as before, to a drop in V^R of 50%. See the appendix for details of the simulation.

to R (i.e. when the second inequality of assumption 7 holds exactly) and lastly when all the rents from FDI asymptotically go to U (i.e. when the first inequality of assumption 7 holds exactly).[19] We assume parameters such that in all cases the investment options are exercised. The model without FDI is very similar to the model of section 2.3: following a collapse in δ^R, the interest rate falls permanently from r_{aut} to $\bar{r} = g^z + \bar{\delta}\theta/(1-\kappa)$ where $\bar{\delta}$ is the fraction of world income that can be capitalized. By now, the consequences are well known: the wealth transfer to U generates a trade deficit, an accumulation of foreign debt, eventually followed by trade surpluses (panel D).

In the presence of FDI, the results are starkly different. Let's start with the long run. The asymptotic effect of FDI is to increase the supply of U-like assets sufficiently to offset the initial shock. This has a strong implication for the path of net foreign assets (panel B): since r_t converges to r_{aut} as long as FDI takes place (Panel C), the Metzler diagram tells us that long run external imbalances disappear asymptotically. This is independent of the cost of ownership of the R trees (κ_P) as long as Assumption 7 is satisfied. The reason is that κ_P controls the distribution of wealth between U and R, leaving total wealth unchanged.

Consider the short run now. The interest rate satisfies:[20]

$$r_t = g^z + \theta \left[\delta \left(x_t^U + x_t^{Rn} \right) + \delta^R x_t^{Ro} \right] - \theta g^n \frac{N_0^R \left[v_t^{Rn} - v_t^{Ro} \right]}{X_t} \tag{28}$$

where x_t^{Rn} (resp. x_t^{Ro}) denote the new (resp. old) R's trees share of world output and v_t^{Rn} (resp. v_t^{Ro}) represent the value of one new (resp. old) R tree. The last term of this equation makes clear that initially $r_t < \bar{r}$ since $v_0^{Rn} > v_0^{Ro}$ and $x_0^{Rn} = 0$. The reason for this last term is the initial increase in asset demand arising from the total flow of financial savings generated by FDI : $g^n \left(V_t^U + N_t^R v_t^{Rn} \right) > g^n V_t$.[21]

In the short run, FDI increases asset demand -which lowers further interest rates; in the long run, it increases asset supply, which brings interest rates back to r_{aut}.

From (20) and (28) we note also that the dynamics of interest rates and asset values are independent of κ_P (as long as FDI takes place). Hence, the initial increase in U's wealth is also independent of the cost of FDI. It follows that U's initial trade imbalance (equal to $X_0^U - \theta W_0^U - I_0^U$) is also independent of κ_P. Indeed, we observe on Panels A and D that U's initial current accounts and trade deficits are the same for different realizations of κ_P.

A lower value of κ_P (higher rents for U) implies a permanently larger trade deficit in U, ranging from 0 to 4% of output (Panel D).

To understand why U runs asymptotic trade deficits as soon as it has strictly positive asymptotic surpluses, consider first the case where U has no FDI rents asymptotically. In that case, U has no asymptotic trade deficit either. Yet, Panel D indicates that U never runs a trade surplus. The reason is that U earns

---

[19]For this simulation, we assume $\kappa = 0$, $g^n = g = 0.03$, $g^z = 0$ and we vary κ_P between 5% and 12%. For comparability, we also choose δ so that $r_{aut} = 6\%$. We obtain $\delta = 0.24$.

[20]See the appendix for a derivation.

[21]In other words, when there is FDI, savings decline less in U and increase more in R. The precise allocation depends upon the value of κ_P. The reason for the additional savings is the future rise in interest rates which depresses current asset values (and hence short run rates have to fall to restore these values).

rents on its FDI investment along the path, which allow it to run trade deficits in every period. In fact, we can define these rents (over total wealth W^U) as:

$$\chi_t = \frac{g^n N_t^R v_t^{Rn} - (\kappa_p + \kappa) X_t^{Rn} - \kappa X_t^{Ro}}{W_t^U}$$

Asymptotically, these rents converge (from above) to

$$\chi_\infty = \left[g^n \frac{\delta}{r_\infty - g^z} - (\kappa_p + \kappa) \right] \frac{X_t^R}{W_t^U} \tag{29}$$

which is equal to zero when the first inequality of assumption 7 holds exactly.

We can now understand why U can run permanent trade deficits: When Assumption 7 holds strictly, intermediation rents remain strictly positive and provide the resources to finance permanent trade deficits.

4   Multiple Goods and Exchange Rates

Up to now, our conclusions have abstracted from (real) exchange rate considerations. However, the main point of this section is to show that adding such dimension to the model does not alter the qualitative (and in some cases quantitative) features of the results. While adding multiple goods allows us to generate exchange rate patterns from our shocks that resemble those observed in recent data —in particular, U appreciates vis a vis both, R and (to a lesser extent) E, when asset markets collapse in R— the behavior of capital flows and interest rates remain largely unchanged with the exception of some attenuation in the $U - E$ context and amplification in some $U - R$ cases.

4.1   Preliminaries

Let us return to the framework in Section 2, without an investment margin, but extend it to consider differentiated goods. Each country i produces one type of good X^i, while its consumers have the following constant elasticity preferences (CES):

$$C^i = \left(\sum_j \gamma_{ij}^{\frac{1}{\sigma}} x^{j \frac{\sigma-1}{\sigma}} \right)^{\frac{\sigma}{\sigma-1}} \tag{30}$$

where σ represents the –constant– elasticity of substitution between the goods from any two countries. The coefficients γ_{ij} measure the strength of preferences for the various goods and satisfy $\sum_j \gamma_{ij} = 1$. Assumption 8 below imposes that agents have a preference for their home good. This assumption is well-established empirically. It also generates relative demand effects that will be important for exchange rate dynamics.

Assumption 8 *(Consumption Home Bias) Each agent has a preference for the home good:* $\gamma_{ii} \equiv \gamma > 0.5$.

Let X^U be the numeraire good and define q^j as the price of good j in terms of good U (with the convention $q^U = 1$). Given (30), the Fisher-ideal price indices are:

$$P^i = \left(\sum_j \gamma_{ij} q^{j(1-\sigma)} \right)^{1/(1-\sigma)}$$

and the real exchange rate between countries i and k is

$$\lambda^{ik} = \frac{P^k}{P^i} = \left(\frac{\sum_j \gamma_{kj} q^{j(1-\sigma)}}{\sum_j \gamma_{ij} q^{j(1-\sigma)}} \right)^{1/(1-\sigma)}$$

This expression highlights the importance of consumption home bias for exchange rate movements: if $\gamma_{ij} = \gamma_{kj}$ for all j, then purchasing power parity obtains and the real exchange rate is equal to 1.

Given CES preferences, the demand for good j by residents of country i satisfy:

$$x^{ij} = \gamma_{ij} C^i \left(\frac{q^j}{P^i} \right)^{-\sigma}, \ \forall i, j$$

and equilibrium in the goods market imposes

$$\sum_i x_{ij} = X_j, \ \forall j.$$

Substituting $P^i C^i = \theta W^i$ (where domestic wealth is now measured in terms of U's good), the equilibrium condition for good i can be rewritten as:

$$\theta \sum_i \gamma_{ij} \frac{W^i}{P^i} \left(\frac{q^j}{P^i} \right)^{-\sigma} = X^j, \ \forall j.$$

4.2   A $U - E$ World

We now specialize the model to a symmetric $U - E$ world, and denote by r_t the instantaneous return in terms of the numeraire. By arbitrage, r_t satisfies

$$r_t V_t^i = \delta q_t^i X_t^i + \dot{V}_t^i$$

while wealth dynamics follow

$$\dot{W}_t^i = (1 - \delta) q_t^i X_t^i + (r_t - \theta) W_t^i.$$

As before, adding across countries and using the equality between global wealth and global asset values, one obtains:

$$W_t = V_t = \frac{X_t}{\theta}$$

where $X_t = X_t^U + q_t^E X_t^E$.

Following the same steps as before, the instantaneous interest rate satisfies:

$$r_t = \frac{\dot{X}_t}{X_t} + \delta\theta.$$

The only notable difference is that the (inverse of the) terms of trade q_t^E –and hence the real exchange rate– enters into the determination of global wealth and of the equilibrium interest rate via X_t.

In turn, the terms of trade are determined by the equilibrium on the market for X^U (by Walras' Law, the market for X^E is also in equilibrium):

$$\theta\gamma W_t^U P_t^{U(\sigma-1)} + \theta (1 - \gamma) W_t^E P_t^{E(\sigma-1)} = X_t^U.$$

29

Let Assumptions 2 and 3 hold, so that the world is initially symmetric with a common rate of growth g, and there is extreme portfolio home bias. Given the symmetry assumption, it is immediate that $q^E = 1$, so that the interest rate satisfies:

$$r = g + \delta\theta$$

while asset values and wealth satisfy

$$V^i = W^i = \frac{X^i}{\theta}.$$

As before, suppose that at $t = 0$ the growth rate of E drops unexpectedly and permanently to:

$$g^E < g.$$

The main initial difference with Section 2 is that now both the interest rate *and* the real exchange rate absorb the shock at impact. To see this, observe that the decline in g^E decreases E's asset values. With Assumption 3 (extreme home portfolio bias), this impoverishes E's residents. Given the consumption-home-bias assumption (Assumption 8), the associated decline in E's consumption falls mostly on the demand for E goods. Equilibrium in the goods markets then requires that q^E falls. This *relative demand effect* implies that U's real exchange rate *appreciates at impact*. It is a direct consequence of both home consumption and portfolio biases. Over time, however, the increase in the *relative supply* of U's good requires that its real exchange rate *depreciates*.

How large is the initial fall and eventual increase in q^E depends on the elasticity of substitution σ. To see this, observe that the relative demands satisfy

$$\frac{x^{iE}}{x^{iU}} \propto (q^E)^{-\sigma}$$

Asymptotically, the ratio of relative demands for at least one country must equal the ratio of relative supply, X^E/X^U. From this, we infer that:

$$\frac{\dot{q}_t^E}{q_t^E} \underset{t\to\infty}{=} \frac{1}{\sigma}(g - g^E).$$

Let us rule out the region $\sigma < 1$ since it implies immiserizing growth. In the feasible region, consider first the $\sigma = 1$ case which yields the starkest departure from the previous section. Given the initial symmetry between E and U, one can show that now terms of trade satisfy

$$q_t^E = \frac{X_t^U}{X_t^E}$$

which implies,

$$x_t^U = \frac{1}{2}.$$

In this extreme case, when growth slows down in E there is no change in the exchange rate at impact, and a gradual increase in q at rate $(g - g^E)$ thereafter. Since the output share is constant, the instantaneous return in terms of X^U is also constant and equal to

$$r = \frac{1}{2}g + \frac{1}{2}\left(g^E + \frac{\dot{q}^E}{q^E}\right) + \delta\theta = g + \delta\theta.$$

One can also check that

$$V_t^i = W_t^i = \frac{q^i X_t^i}{\theta}.$$

Hence neither country needs to run current account imbalances in response to the collapse in g^E. The reason is that the terms of trade offset perfectly the relative decline in output growth, leaving relative wealth and relative output unchanged (when measured in the same units). Log preferences eliminate the model's dynamics.[22]

Consider now the more realistic case where $\sigma > 1$. From the previous discussion, we infer that q^E increases at a smaller rate than the growth differential. For instance, with $\sigma = 4$ —not an unreasonable value[23]— and a growth differential of 1 percent per year, the model implies that U's terms of trade would worsen at 0.25 percent per year. This implies an even slower real exchange rate depreciation, which eventually converges to a steady state value of $((1 - \gamma)/\gamma)^{1/(1-\sigma)}$.

We can prove a result similar to Proposition 1 and the associated Metzler diagram in presence of exchange rates. From $r_t = \dot{X}_t/X_t + \delta\theta$, we have

$$r_t = g x_t^U + \left(g^E + \dot{q}_t/q_t\right)\left(1 - x_t^U\right) + \delta\theta.$$

Since x_t^U tends to 1, we obtain:

$$\lim_{t \to \infty} r_t = g + \delta\theta = r_{aut}^U.$$

From

$$\dot{W}_t^E = (r_t - \theta) W_t^E + (1 - \delta) q_t^E X_t^E$$
$$r_t V_t^E = \delta q_t X_t^E + \dot{V}_t^E$$

it is apparent that

$$\frac{W_t^E}{q_t^E X_t^E} \xrightarrow[t \to \infty]{} \frac{(1 - \delta)}{\theta + \left(g^E + \frac{1}{\sigma}(g - g^E)\right) - r_{aut}^U}$$
$$\frac{V_t^E}{q_t^E X_t^E} \xrightarrow[t \to \infty]{} \frac{\delta}{r_{aut}^U - \left(g^E + \frac{1}{\sigma}(g - g^E)\right)}$$

Thus, the asymptotic wealth and asset values are similar to those of Proposition 1, the only difference being that g^E has to be replaced by $g^E + \frac{1}{\sigma}(g - g^E) < g^U$.

By a reasoning analogous to that in Lemma 1, we obtain:

$$\frac{CA_t^U}{q_t^E X_t^E} = -\frac{CA_t^E}{q_t^E X_t^E} \xrightarrow[t \to \infty]{} \left(g^E + \frac{1}{\sigma}(g - g^E)\right)\left[\frac{\delta}{r_{aut}^U - \left(g^E + \frac{1}{\sigma}(g - g^E)\right)} - \frac{(1 - \delta)}{\theta + \left(g^E + \frac{1}{\sigma}(g - g^E)\right) - r_{aut}^U}\right] \le 0$$

As we discussed above, when $\sigma = 1$ there is no current account deficit. At the other extreme, when σ tends to infinity we recover the deficits from Proposition 1 since there is no offsetting long-run exchange

---

[22]This well-known result was first shown by Cole and Obstfeld (1991).

[23]See later in this section for a discussion of the calibration of σ.
Figure 8: A Collapse in g^E in the two-good model

rate movement. While there can be non-monotonicities in the intermediate region, the general message is apparent: The possibility of *long-run* exchange rate movements attenuates rather than exacerbates the wealth effects associated with differential growth and hence attenuates asymptotic current account deficits. The main reason behind the latter is that the reduced wealth effects at impact when $\sigma < \infty$ leads to smaller initial trade deficits in U and hence smaller accumulated net external liabilities.

Figure 8 presents a simulation of a decline in g^E in the two-goods model when $\sigma = 4$ and $\gamma = 0.9$.[24] It confirms our conclusions from the one-good model –see Figure 3.

[24]Feenstra (1994) finds a value of 4 for σ while Broda and Weinstein (2004) report estimates ranging from 17 at 7-digit between 1972-1988 to 4 for 3-digit goods in 1990-2001. Obstfeld and Rogoff (2004) use an elasticity of 2 while Obstfeld and Rogoff (2000) used a value of 6. Obstfeld and Rogoff (2004) use a weight on domestic tradeable of 0.7. But they also assume a share of expenditure on non-tradeable equal to 0.75. This corresponds to a share of domestic consumption on domestic goods γ of 0.925, not far from our 0.9.

Comparing panels A-D in both figures, we observe that relative price movements limit the size of the current account deficit (Panel A, 8.2 percent versus 17 percent in the single good model) and limit accordingly the build-up in net foreign debt (Panel B, -57 percent after 24 years versus -75 percent of output after 15 years in the single good model). Accordingly, the increase in the share of U in global portfolios is more muted (Panel D). Panel C reports the world's real instantaneous rates of return, defined as the output-weighted average of both countries real returns. The trajectory of the world real interest rates is very similar to the one obtained in panel C in figure 3: from 6 percent, the world interest rate drops to 5.41 percent on impact, then climbs very slowly back toward 6 percent. Finally, Panel E reports the real exchange rate $\lambda = P^E/P^U$. On impact λ appreciates by about 7.8 percent, then gradually but persistently depreciates. Importantly, in our model it is the latter effect that dominates (dampens) wealth effects and hence limits the initial current account deficits in U.

4.3 A $U - R$ World

Consider now the interaction between U and R. As before, let's consider a scenario where R's ability to capitalize financial assets drops from δ to $\delta^R < \delta$ while $g^R = g$.

Following the same steps as before, we obtain:

$$V_t = W_t = \frac{X_t}{\theta}$$

where $X_t = X_t^U + q_t^R X_t^R$, $V_t = V_t^U + V_t^R$ and $W_t = W_t^U + W_t^R$. The instantaneous rate of return now satisfies:

$$r_t = r_{aut}^U + \left(1 - x_t^U\right)\left(\frac{\dot{q}_t^R}{q_t^R} - \theta(\delta - \delta^R)\right)$$

which is similar to equation (16), except for the rate of change of the terms of trade.

Since output growth is the same in both countries, a reasoning similar to the previous section implies that $\dot{q}_t^R/q_t^R = 0$ asymptotically. The absence of relative supply effect implies that the long run terms of trade are stable. On impact, however, the relative demand effect is still present: the decline in δ^R reduces the value of R's financial assets which, under portfolio home bias, reduces R's financial wealth. Finally, due to consumption home bias, the decline in financial wealth in R reduces disproportionately the relative demand for R's good and induces a decline in q^R.

Asymptotically, substituting $\dot{q}_t^R/q_t^R = 0$ into the expression for r_t, we see that the interest rate reaches the value:

$$\lim_{t\to\infty} r_t = r_\infty^+ = r_{aut}^U - \left(1 - x_\infty^U\right)(\delta - \delta^R)\theta < r_{aut}^U$$

where x_∞^U represents the asymptotic share of U's output. Now Lemma 1 applies, so that

$$\frac{V_t^R}{q_t^R X_t^R} \underset{t\to\infty}{\to} \frac{\delta^R}{r_\infty^+ - g}; \qquad \frac{V_t^U}{X_t^U} \underset{t\to\infty}{\to} \frac{\delta}{r_\infty^+ - g},$$

$$\frac{W_t^R}{q_t^R X_t^R} \underset{t\to\infty}{\to} \frac{1 - \delta^R}{\theta + g - r_\infty^+}; \qquad \frac{W_t^U}{X_t^U} \underset{t\to\infty}{\to} \frac{1 - \delta}{\theta + g - r_\infty^+}$$

33

and the asymptotic current account satisfies

$$\frac{CA_t^U}{X_t^U} \xrightarrow{t \to \infty} g \left(\frac{1-\delta}{\theta + g - r_\infty^+} - \frac{\delta}{r_\infty^+ - g} \right) < 0.$$

Since $r_{aut}^U > r_\infty^+$, U runs a permanent current account deficit.

The results of Proposition 2 carry through with one exception: the asymptotic output share x_∞^U may differ from the initial output share x_0^U. It is immediate that the current account deficit will be larger if $r_\infty^+ < r^+$, or, from the formula for r_∞^+, if

$$x_\infty^U < x_0^U.$$

Since $x_t^U = X_0^U / \left(q_t^R X_0^R + X_0^U \right)$, this is equivalent to $q_\infty^R > q_0^R$ or $\lambda_\infty > \lambda_0$. If the real exchange rate depreciates asymptotically, which it does in our simulations, the asymptotic current account worsens, compared to the single good case.

The conventional rebalancing channel has implications for exchange rate movements but does not affect the core story for capital flows, which lies somewhere else in global asset markets.[25] In fact, although small for our calibrated parameters, adding the exchange rate dimension allows U to run larger asymptotic current account deficits and hold larger net foreign liabilities. The reason is that the long run depreciation reduces U's share of output (x_∞^U). This is equivalent to a further reduction in the global supply of assets and pushes world interest rates lower (Panel C), reducing U's borrowing costs.

Finally, figure 9 presents the results of a simulation similar to Figure 5. Panel E demonstrates that the real exchange rate appreciates on impact by 17 percent, then depreciates slowly, returning to λ_{0-} in 12 years, then depreciating by another 3.5 percent. Given the previous discussion, the long run depreciation of the real exchange rate implies that the asymptotic current account deficits are (slightly) larger than in the single good model (-2.96 percent versus -2.85 percent in the single good model) with a correspondingly higher permanent accumulation of net foreign liabilities (99% of output versus 95%). Panel C shows that our conclusion with respect to the decline in interest rates from the single good model remains largely unchanged.

4.4   The Three Regions World

For completeness, we conclude this section by integrating the three regions. The results are as expected, with the additional insight that since a crash in δ^R has a disproportionate effect on V^U relative to V^E when $g^E < g$, and, given financial home bias, on W^U, at impact U's currency appreciates not only vis-a-vis R's currency but also vis-a-vis E's currency (due to consumption-home-bias). However, this effect is small relative to the depreciation of R exchange vis-a-vis both U and E.

Figure 10 reports the bilateral real exchange rates between U, E and R. We start the economy in a symmetric equilibrium ($g^i = g$ and $\delta^i = \delta$), with $x_0^U = x_0^E = 0.425$ and $x_0^R = 0.15$.[26] We then reduce E's

---

[25]The rebalancing channel refers to the mechanism whereby the rapid accumulation of claims on U by R residents, together with the consumption home bias assumption requires a future a depreciation of the real exchange rate.

[26]We also assume that the home good preferences are such that $\gamma_{ii} = 0.9$, $\gamma_{ij} = 0.05$ for $i \neq j$.

Panel E: Real Exchange Rate

Figure 9: A Collapse in δ^R in the two-good model

growth at $t = 0$. This leads to an immediate appreciation of $U's$ real exchange rate, as in section 4.2. Then, at $t = 5$, we decrease δ^R so that V^R decreases by 50%. The figure confirms our intuition: the crash in δ^R increases V^U/V^E, which increases the relative demand for good U and appreciates $U's$ real exchange rate relative to E by 2%.

5 Reversals

Until now, we have only considered the effect of permanent shocks to growth and financial development on global allocations. While indeed many of the factors behind growth and financial development differential seem structural, it is not unconceivable —and is certainly desirable— that they dissipate over time. Convergence forces may prevent E from growing at a permanently lower rate than U. Similarly, R countries are
35

Figure 10: Bilateral Real Exchange Rates in the U-E-R model. Collapse in g^E at $t = 0$ followed by a collapse in δ^R at $t = 5$

likely to develop financially and eventually increase their domestic supply of financial assets (section 3 shows how this can occur through direct investment). This section considers the effects of reversals in the forces behind 'global imbalances.' Specifically, we study the consequences of an increase in δ^R in a $U - R$ world.[27] We consider two scenarios. In the first one, financial development in R *unexpectedly* reverts to δ twenty years after the initial shock (Figure 11). For the first twenty years, the shock is perceived as permanent, so the dynamics coincide with Figure 5. The increase in δ^R at $t = 20$ is now associated with a sharp reversal in the current account deficit in U, as interest rates increase back to r_{aut}, and R residents rapidly decumulate their financial claims on U. Importantly, this reversal generates a substantial positive valuation effect for U residents, equal to about 22% of U's output (panel B).

This figure highlights that our setup can accommodate a sharp reversal in the current account, but this reversal would stem from a reversal of the fundamental causes that triggered the initial shift (here a sudden increase in δ^R), and not from a spontaneous correction of an "anomaly", as the conventional view would have it.

A more likely scenario is that R (or E) turns the corner gradually. This is our second experiment: the reversal is now *expected* as of time $t = 0$ (Figure 12). Expectations of a reversal lead to a smaller decline in asset values in R relative to U, hence a smaller decline in relative wealth and smaller current account deficits in U (from -20 % of GDP in Figures 5 and 11 to -8 %). Further, these deficits are *gradually* eliminated as asset values in R and U converge back up to their pre-shock level. U eventually runs current account surpluses (after 10 years) as R residents start decumulating U's assets in anticipation of the reversal in δ^R. Yet these surpluses remain small relative to the initial current account deficits.

The message is clear: expectations of future financial development (or growth) increase asset values in R

[27]The case of a growth reversal in a $U - E$ world is similar.

Figure 11: A Collapse in δ^R, followed by an *unexpected* reversal at $t = 20$

and sustain a gradual rebalancing (the strong recent performance of stock markets in Germany, Japan, or emerging Asia and oil producing countries can be interpreted in this light). Yet, these are only hopes. Until financial development takes hold (or growth resumes), global interest rates remain depressed (see panel C), and this limits the rebalancing from U to R.

6 Final Remarks

In this paper we have proposed a framework to analyze the effects of different structural shocks on global capital flows, portfolio shares and interest rates. The framework highlights the connection between a region's relative fundamentals – in particular, its growth potential and the quality (or acceptance) of its financial assets – and its ability to produce financial assets for global savers.

We used the framework to discuss two shocks that we view as particularly relevant in explaining recent "global imbalances" and the "interest rate conundrum." The first one is a sustained growth slowdown in E; The second one is a collapse in the capacity to generate assets in R. The former captures well the effect of a relative slowdown in the Euro area and Japan. The second captures aspects of the Japanese bubble crash in the early 1990s and the developments in much of emerging markets and newly industrialized economies of Asia in the aftermath of the Asian and Russian crises at the end of the 1990s. We also explored the global effects of the interaction between R's limited financial markets and its fast potential growth. All these effects point in the same direction: To a sustained reallocation of savings toward U and to lower interest rates.
Figure 12: A Collapse in δ^R, followed by an *expected* reversal at $t = 20$

The framework is flexible enough to explore a variety of experiments and issues that have been postulated in the "global imbalances" debate. For example, a dimension we did not develop in the main text but is trivial to analyze is that of an increase in a regions' saving propensity (for example, a decline in θ^R). The implications would be similar in terms of the path of capital flows, measured saving rates, interest rates and the interaction with fast growth in R, as those following a crash in δ^R. However the implications would be entirely different for V^R: While a drop in δ^R comes with an initial crash in R's asset prices, an increase in the propensity to save does the opposite. This distinction is important since the dramatic acceleration in capital flows toward the US in the late 1990s from R came with a crash rather a rise in asset values in R. This is not to say that a drop in θ^R is not part of the story, as it is a convenient short-cut to represent the more recent increase in saving rates by commodity producing economies (which have come with high local asset prices) or even to capture demographic factors. Moreover, such drop further strengthens the downward pressure on long rates when combined with fast growth in R. However, in terms of timing it is the crash in δ^R that most likely started the massive flows from R to U.

One could also model some of the aspects of fiscal deficits in the US as an increase in θ^U. This would indeed lead to current account deficits in U but it would increase rather than reduce interest rates, and hence it is probably not the main factor behind current "global imbalances." Instead, this angle offers a better representation of the current account deficits of the US during the 1980s.

Similarly, one could model the process of globalization as one in which regions are gradually allowed to participate in global capital markets. In that case, one could generate a downward trend in global interest

38

rates as low δ^R economies are integrated. This probably accounts for some of the downward pressure observed on rates since the 1990s.

Finally, a word of caution. Our framework also highlights that the current configuration of global asymmetries is likely to continue building the already large net external liabilities of U. Leverage always comes with risks. We have already illustrated within our framework how an unexpected reversal in the relative growth advantage of U vis-a-vis E, or in R's financial underdevelopment (perhaps the most likely reversal channel), would lead to a sharp reversal in capital flows, interest rates and exchange rates. One could also go outside the model and add a credit-risk concern with U's liabilities and generate a more harmful reversal. Our model has little to say about the latter possibility, although it seems remote. Moreover, one of our main points has been that such risk does *not* follow as an unavoidable outcome of the current scenario, as the latter is consistent with current global asymmetries in growth potential and financial development.

A   Proofs

A.1   Proof of Lemma 1

We have

$$
\begin{aligned}
V_t &= \int_t^\infty \delta X_s e^{-\int_t^s r_u du} ds = \delta X_t \int_t^\infty e^{-\int_t^s (r_u - g) du} ds \\
W_t &= W_0 e^{\int_0^t (r_s - \theta) ds} + \int_0^t (1 - \delta) X_s e^{\int_s^t (r_u - \theta) du} ds \\
&= (1 - \delta) X_t \left[\frac{W_0}{(1 - \delta) X_t} e^{\int_0^t (r_s - \theta) ds} + \int_0^t e^{\int_s^t (r_u - \theta - g) du} ds \right]
\end{aligned}
$$

The Lemma follows from the fact that

$$
\begin{aligned}
\lim_{t \to \infty} \int_t^\infty e^{-\int_t^s (r_u - g) du} ds &= \frac{1}{r - g} \\
\lim_{t \to \infty} \int_0^t e^{\int_s^t (r_u - \theta - g) du} ds &= \frac{1}{g + \theta - r}
\end{aligned}
$$

and

$$
\lim_{t \to \infty} \frac{W_0}{(1 - \delta) X_t} e^{\int_0^t (r_s - \theta) ds} = 0
$$

when $g < r < g + \theta$.

A.2   Proof of Lemma 3

By definition, we can write:

$$
W_t^j = \alpha_t^{j,i} V_t^i + (1 - \alpha_t^{i,j}) V_t^j
$$

and the net asset demand as:

$$
W_t^j - V_t^j = \alpha_t^{j,i} V_t^i - \alpha_t^{i,j} V_t^j
$$

so that:

$$
\begin{aligned}
CA_t^i &= \dot{W}_t^i - \dot{V}_t^i \\
&= (1 - \delta) X_t^i - \theta W_t^i + r_t W_t^i - \dot{V}_t^i \\
&= (1 - \delta) X_t^i - \theta W_t^i + r_t (W_t^i - V_t^i) + \delta X_t^i \\
&= X_t^i - \theta W_t^i + r_t (\alpha_t^{i,j} V_t^j - \alpha_t^{j,i} V_t^i)
\end{aligned}
$$

A.3   The role of assumption 4

Suppose that assumption 4 does not hold. This appendix shows that the essence of our analysis is not affected by this change, although the expressions are less friendly, if we are willing to make the minimal assumption that $g^E > 0$, so that $g > (1 - \delta)\theta$ if Assumption 4 does not hold.

Let $x_t^u \equiv X_t^U/X_t$ be the relative size of country U's endowment. Since $X_0^U = X_0^E$, we have

$$x_t^u = \frac{X_0^U e^{gt}}{X_0^U e^{gt} + X_0^E e^{g^E t}} = \frac{1}{1 + e^{-(g-g^E)t}}$$

It will prove useful to compute $\int_0^t x_s^u ds$ in closed form

$$
\begin{aligned}
\int_0^t x_s^u ds &= \int_0^t \frac{1}{1 + e^{-(g-g^E)x}} dx = \frac{1}{g - g^E} \int_{e^{-(g-g^E)t}}^1 \frac{1}{u(1+u)} du \\
&= \frac{1}{g - g^E} \left[\ln\left(\frac{u}{1+u}\right) \right]_{e^{-(g-g^E)t}}^1 = \frac{1}{g - g^E} \ln\left(\frac{1 + e^{(g-g^E)t}}{2}\right)
\end{aligned}
$$

Note that we can express $r_t = \frac{\dot{X}_t}{X_t} + \delta\theta$ as

$$r_t = \delta\theta + g^E + x_t^U \left(g - g^E\right)$$

Solving forward the differential equation for V_t^E, we get

$$
\begin{aligned}
V_t^E &= \int_t^\infty \delta X_s^E e^{-\int_t^s r_u du} ds \\
&= \int_t^\infty e^{-\delta\theta(s-t) - g^E(s-t) - (g-g^E)\int_t^s x_h^u dh} \delta X_t^E e^{g^E(s-t)} ds \\
&= \delta X_t^E \int_t^\infty e^{-\delta\theta(s-t) - (g-g^E)\int_t^s x_h^u dh} ds \\
&= \delta X_t^E \int_t^\infty \frac{1 + e^{-(g-g^E)t}}{1 + e^{-(g-g^E)s}} e^{-(g-g^E+\delta\theta)(s-t)} ds
\end{aligned}
$$

Similarly, we can solve forward the differential equation for V_t^U

$$
\begin{aligned}
V_t^U &= \int_t^\infty \delta X_s^U e^{-\int_t^s r_u du} ds \\
&= \int_t^\infty e^{-\delta\theta(s-t) - g^E(s-t) - (g-g^E)\int_t^s x_h^u dh} \delta X_t^U e^{g(s-t)} ds \\
&= \delta X_t^U \int_t^\infty e^{-\delta\theta(s-t) + (g-g^E)(s-t) - (g-g^E)\int_t^s x_h^u dh} ds \\
&= \delta X_t^U \int_t^\infty \frac{1 + e^{-(g-g^E)t}}{1 + e^{-(g-g^E)s}} e^{-\delta\theta(s-t)} ds
\end{aligned}
$$

We can also solve the differential equation for W_t^E and W_t^U, with initial conditions W_{0+}^E and W_{0+}^U

$$W_t^E \;=\; W_{0^+}^E e^{\int_0^t (r_s-\theta)ds} + \int_0^t (1-\delta)X_s^E e^{\int_s^t (r_u-\theta)du}$$

$$=\; W_{0^+}^E \exp\left[-(1-\delta)\theta t + g^E t + (g-g^E)\int_0^t x_s^u ds\right]$$

$$+(1-\delta)X_t^E \int_0^t \exp\left[-(1-\delta)\theta(t-s) + (g-g^E)\int_s^t x_h^u dh\right]ds$$

$$=\; W_{0^+}^E \frac{e^{g^E t}+e^{gt}}{2}e^{-(1-\delta)\theta t} + (1-\delta)X_t^E \int_0^t \frac{1+e^{-(g-g^E)t}}{1+e^{-(g-g^E)s}}e^{(g-g^E-(1-\delta)\theta)(t-s)}ds$$

$$W_t^U \;=\; W_{0^+}^U e^{\int_0^t (r_s-\theta)ds} + \int_0^t (1-\delta)X_s^U e^{\int_s^t (r_u-\theta)du}$$

$$=\; W_{0^+}^U \exp\left[-(1-\delta)\theta t + g^E t + (g-g^E)\int_0^t x_s^u ds\right]$$

$$+(1-\delta)X_t^U \int_0^t \exp\left[-(1-\delta)\theta(t-s) - (g-g^E)(t-s) + (g-g^E)\int_s^t x_h^u dh\right]ds$$

$$=\; W_{0^+}^U \frac{e^{g^E t}+e^{gt}}{2}e^{-(1-\delta)\theta t} + (1-\delta)X_t^U \int_0^t \frac{1+e^{-(g-g^E)t}}{1+e^{-(g-g^E)s}}e^{-(1-\delta)\theta(t-s)}ds$$

Hence

$$V_t^E \;=\; \delta X_t^E \int_t^\infty \frac{1+e^{-(g-g^E)t}}{1+e^{-(g-g^E)s}}e^{-(g-g^E+\delta\theta)(s-t)}ds$$

$$\underset{t\to\infty}{\sim}\; \frac{\delta X_t^E}{g-g^E+\delta\theta}$$

$$W_t^E \;=\; W_{0^+}^E \frac{e^{g^E t}+e^{gt}}{2}e^{-(1-\delta)\theta t} + (1-\delta)X_t^E \int_0^t \frac{1+e^{-(g-g^E)t}}{1+e^{-(g-g^E)s}}e^{(g-g^E-(1-\delta)\theta)(t-s)}ds$$

$$\underset{t\to\infty}{\sim}\; W_{0^+}^E \frac{e^{(g-(1-\delta)\theta)t}}{2} + (1-\delta)X_0^E e^{(g-(1-\delta)\theta)t}\int_0^t \frac{1+e^{-(g-g^E)t}}{1+e^{-(g-g^E)s}}e^{-(g-g^E-(1-\delta)\theta)s}ds$$

$$\underset{t\to\infty}{\sim}\; W_{0^+}^E \frac{e^{(g-(1-\delta)\theta)t}}{2} + (1-\delta)X_0^E e^{(g-(1-\delta)\theta)t}\int_0^\infty \frac{1}{1+e^{-(g-g^E)s}}e^{-(g-g^E-(1-\delta)\theta)s}ds$$

Therefore, it is easy to see that

$$V_t^E \underset{t\to\infty}{\sim} \frac{\delta X_t^E}{g-g^E+\delta\theta}$$

$$\dot{V}_t^E \underset{t\to\infty}{\sim} \frac{\delta g^E X_t^E}{g-g^E+\delta\theta}$$

$$W_t^E \underset{t\to\infty}{\sim} e^{(g-(1-\delta)\theta)t}\left(W_{0^+}^E + (1-\delta)X_0^E\right)\left(\frac{1}{2} + \int_0^\infty \frac{1}{1+e^{-(g-g^E)s}}e^{-(g-g^E-(1-\delta)\theta)s}ds\right)$$

$$\dot{W}_t^E \underset{t\to\infty}{\sim} (g-(1-\delta)\theta)e^{(g-(1-\delta)\theta)t}\left(W_{0^+}^E + (1-\delta)X_0^E\right)\left(\frac{1}{2} + \int_0^\infty \frac{1}{1+e^{-(g-g^E)s}}e^{-(g-g^E-(1-\delta)\theta)s}ds\right)$$

Hence

$$CA_t^U \underset{t\to\infty}{\sim} -\dot{W}_t^E$$

$$CA_t^U \underset{t\to\infty}{\sim} -(g-(1-\delta)\theta)e^{(g-(1-\delta)\theta)t}\left(W_{0^+}^E + (1-\delta)X_0^E\right)\left(\frac{1}{2} + \int_0^\infty \frac{1}{1+e^{-(g-g^E)s}}e^{-(g-g^E-(1-\delta)\theta)s}ds\right)$$

Now the decomposition is:

$$\theta W_t^E - X_t^E \underset{t\to\infty}{\sim} \theta W_t^E$$

$$r_t(V_t^E - W_t^E) \underset{t\to\infty}{\sim} -(g + \delta\theta)W_t^E$$

Therefore, the trade balance is positive while income flows are negative (and larger in absolute value than the trade balance), as in the main text.

A.4 Proof of proposition 3

The first inequality of the first statement follows directly from $(\delta - \delta^R) > 0$, as in Proposition 2. The second inequality follows from the fact that x_t^U declines over time. Asymptotically, r_t converges to r_{aut}^R.

From Lemma 1, we know that

$$\frac{CA_t^U}{X_t^U} \underset{\substack{t \to \infty \\ g^R > g}}{\to} -g\frac{r_{aut}^U - r_{aut}^R}{\left(g + \theta - r_{aut}^R\right)\left(r_{aut}^R - g\right)} < 0$$

On the other hand, from Proposition 2 we have that

$$\frac{CA_t^U}{X_t^U} \underset{\substack{t \to \infty \\ g^R = g}}{\to} -g\frac{r_{aut}^U - r^+}{\left(g + \theta - r^+\right)\left(r^+ - g\right)} < 0$$

where $r^+ = r_{aut}^U - \theta\left(1 - x_0^U\right)\left(\delta - \delta^R\right)$ (see (18)). From assumption 5, $r^+ > r_{aut}^R$ and the second statement in the proposition now follows since

$$\frac{r - r_{aut}^U}{\left(g + \theta - r\right)\left(r - g\right)} = \frac{1 - \delta}{g + \theta - r} - \frac{\delta}{r - g}$$

is increasing with respect to r.

A.5 The $U - E - R$ model

In this case the equations describing the dynamics of each country's wealth are

$$\dot{W}_t^U = -\theta W_t^U + (1 - \delta)X_t^U + r_t W_t^U$$

$$\dot{W}_t^E = -\theta W_t^E + (1 - \delta)X_t^E + r_t W_t^E$$

$$\dot{W}_t^R = -\theta W^R + (1 - \delta^R)X_t^R + r_t W_t^R$$

which aggregate to the following differential equation for global wealth

$$\dot{W}_t = \left(1 - \delta + \left(\delta - \delta^R\right)x_t^R\right)X_t + (r_t - \theta)W_t \tag{31}$$

45

Similarly, the asset pricing equations for each country's tree are

$$r_t V_t^U = \delta X_t^U + \dot{V}_t^U$$
$$r_t V_t^E = \delta X_t^E + \dot{V}_t^E$$
$$r_t V_t^R = \delta^R X_t^R + \dot{V}_t^R$$

which imply the following equation for the total value of world assets

$$r_t V_t = \left(\delta - \left(\delta - \delta^R\right) x_t^R\right) X_t + \dot{V}_t \tag{32}$$

As usual, investment equals savings in the world market:

$$W_t = V_t \tag{33}$$

which implies a goods market clearing condition

$$W_t = \frac{X_t}{\theta} \tag{34}$$

The equilibrium interest rate can be solved for

$$
\begin{aligned}
r_t &= \frac{\dot{X}_t}{X_t} + \theta\left(\delta(1 - x_t^R) + \delta^R x_t^R\right) \\
&= x_t^U g^U + x_t^E g^E + x_t^R g^R + \theta\left(\delta(1 - x_t^R) + \delta^R x_t^R\right) \\
&= x_t^U\left(g^U + \delta\theta\right) + x_t^E\left(g^E + \delta\theta\right) + x_t^R(g^R + \delta^R\theta)
\end{aligned}
$$

Hence the world interest rate is a average of $g^U + \delta\theta$, $g^E + \delta\theta$ and $g^R + \delta^R\theta$ with weights given by the

relative size of the endowment of each country.

A.6 Proof of proposition 4

Define r_∞ the asymptotic interest rate. $r_{aut}^R \le r_\infty < r_{aut}^U$ with equality when $g^R > g$. Note that:

$$W_t^E \underset{t\to\infty}{\sim} \frac{(1-\delta)X_t^E}{g^E + \theta - r_\infty}$$
$$W_t^U \underset{t\to\infty}{\sim} \frac{(1-\delta)X_t^U}{g + \theta - r_\infty}$$
$$W_t^R \underset{t\to\infty}{\sim} \frac{(1-\delta^R)X_t^R}{g^R + \theta - r_\infty}$$

and

$$V_t^E \underset{t\to\infty}{\sim} \frac{\delta X_t^E}{r_\infty - g^E}$$
$$V_t^U \underset{t\to\infty}{\sim} \frac{\delta X_t^U}{r_\infty - g}$$
$$V_t^R \underset{t\to\infty}{\sim} \frac{\delta^R X_t^R}{r_\infty - g^R}$$

46

Hence

$$\frac{\delta^R}{V_t^E}\frac{\partial V_t^E}{\partial \delta^R} = \frac{\delta^R}{r_\infty - g^E}\cdot\frac{\partial r_\infty}{\partial \delta^R}$$

$$\frac{\delta^R}{V_t^U}\frac{\partial V_t^U}{\partial \delta^R} = \frac{\delta^R}{r_\infty - g}\cdot\frac{\partial r_\infty}{\partial \delta^R}$$

which implies

$$\frac{\frac{\delta^R}{V_t^U}\frac{\partial V_t^U}{\partial \delta^R}}{\frac{\delta^R}{V_t^E}\frac{\partial V_t^E}{\partial \delta^R}} = \frac{r_\infty - g^E}{r_\infty - g} = 1 + \frac{g - g^E}{r_\infty - g}$$

That is, the long run proportional increase in the value of assets following a collapse in δ^R is larger in U than in E. The results on the current account follow immediately from its definition and the fact that asymptotic wealths are less sensitive than initial wealth to interest rate changes.

A.7 Proof of proposition 5

Let us first focus on the first claim in the proposition. In situation 1, we have

$$\dot{W}_t = \left(1 - \kappa x_t^U\right)\frac{\dot{X}_t}{\theta} - \kappa \dot{x}_t^U \frac{X_t}{\theta}$$

$$= \frac{X_t}{\theta}\left[g^n x_t^U + g^z - \kappa x_t^U g\right]$$

Substituting into the asset equation we solve for the interest rate:

$$r_t = g^z + \frac{\theta\bar{\delta}_t}{1 - \kappa x_t^U} + \frac{g^n x_t^U}{1 - \kappa x_t^U}\left[1 - \kappa - \theta\frac{V_t^U}{X_t^U}\right]$$

where $\bar{\delta}_t = \delta x_t^U + \delta^R x_t^R$. Comparing the interest rate at time 0 when there is no investment collapse $(r_0 = g^z + \theta\bar{\delta}_0/(1 - \kappa))$ and where there is an investment collapse, the difference in interest rates is

$$\Delta r_0 = -\kappa\theta\bar{\delta}_0\frac{1 - x_0^U}{\left(1 - \kappa x_0^U\right)(1 - \kappa)} + \frac{g^n x_0^U}{1 - \kappa x_0^U}\left[1 - \kappa - \theta\frac{V_0^U}{X_0^U}\right]$$

and this is negative because each term is negative (since U is a borrower, we know that $\kappa X_0^U + \theta W_0^U = I_0^U + C_0^U > X_t^U$). This proves the first claim in the proposition.

Let us now prove the second claim in the proposition. To distinguish variables under our counterfactual situation 2, we adopt the convention to underline those variables. We have

$$V_{0+} = (1 - \kappa\frac{X_0^U}{X_0})\frac{X_0}{\theta} \text{ and}$$

$$V_{0+}^R = \frac{\delta^R X_0^R}{\delta^R X_0^R + \delta X_0^U}V_{0+}.$$

Similarly

$$\underline{V}_{0+} = (1 - \kappa)\frac{X_0}{\theta} = V_{0+} - \kappa\frac{X_t^R}{\theta} \text{ and}$$

$$\underline{V}_{0+}^R = \frac{\delta^R X_0^R}{\delta^R X_0^R + \delta X_0^U}\underline{V}_{0+}.$$

47

Hence

$$V_{0+}^R - \underline{V}_{0+}^R = \frac{\delta^R X_0^R}{\delta^R X_0^R + \delta X_0^U}(\underline{V}_{0+} - V_{0+}) = \frac{\delta^R X_0^R}{\delta^R X_0^R + \delta X_0^U}\kappa\frac{X_0^R}{\theta}$$

$$= \frac{V_{0+}^R}{V_{0+}}\kappa\frac{X_0^R}{\theta}$$

Let us first consider situation 1. Assuming extreme home bias, at $t = 0^+$, we have,

$$TB_{0+}^U = CA_{0+}^U = \theta W_{0+}^R - X_0^R = \theta V_{0+}^R - X_0^R$$

Let us now analyze situation 2.

$$\underline{TB}_{0+}^U = \underline{CA}_{0+}^U = \theta\underline{W}_{0+}^R - (1-\kappa)X_0^R = \theta\underline{V}_{0+}^R - (1-\kappa)X_0^R$$

$$= \theta(V_{0+}^R - \kappa\frac{X_0^R}{\theta}\frac{V_{0+}^R}{V_{0+}}) - (1-\kappa)X_0^R$$

$$= \theta V_{0+}^R - X_0^R(1 - \kappa(1 - \frac{V_{0+}^R}{V_{0+}}))$$

Hence

$$CA_{0+}^U < \underline{CA}_{0+}^U$$

and

$$TB_{0+}^U < \underline{TB}_{0+}^U$$

This proves the second claim in the proposition.

A.8 Investment and gross flows

We need to distinguish between the old trees (with δ^R) and the new trees. Define v_t^{Ro} the value of an old R tree, v_t^{Rn} the value of a new R tree and v_t^U the value of a U tree. We have

$$r_t v_t^{Ro} = \delta^R Z_t^R + \dot{v}_t^{Ro}$$

$$r_t v_t^{Rn} = \delta Z_t^R + \dot{v}_t^{Rn}$$

$$r_t v_t^U = \delta Z_t^U + \dot{v}_t^U$$

The aggregate value of U trees is $V_t^U = N_t^U v_t^U$ and satisfies

$$r_t V_t^U = \delta X_t^U + \dot{V}_t^U - g^n V_t^U$$

The aggregate value of new trees in R is $V_t^{Rn} = (N_t^R - N_0^R) v_t^{Rn}$ and satisfies

$$r_t V_t^{Rn} = \delta(N_t^R - N_0^R)Z_t^R + (N_t^R - N_0^R)\dot{v}_t^{Rn}$$

$$= \delta X_t^{Rn} + \dot{V}_t^{Rn} - g^n N_t^R v_t^{Rn}$$

Finally, define the aggregate value of the old trees in R as $V_t^{Ro} = N_0^R v_t^{Ro}$. It satisfies:

$$r_t V_t^{Ro} = \delta^R X_t^{Ro} + \dot{V}_t^{Ro}$$

48

Aggregate wealth then evolves according to

$$r_t V_t = \delta \left(X_t^U + X_t^{Rn} \right) + \delta^R X_t^{Ro} + \dot{V}_t - g^n V_t^U - g^n N_t^R v_t^{Rn}$$

Let's now consider wealth accumulation equations:

$$
\begin{aligned}
\dot{W}_t^U &= (r_t - \theta) W_t^U + (1 - \delta) X_t^U + g^n V_t^U + g^n N_t^R v_t^{Rn} - P_t - I_t \\
\dot{W}_t^R &= (r_t - \theta) W_t^R + (1 - \delta) X_t^{Rn} + \left(1 - \delta^R \right) X_t^{Ro} + P_t
\end{aligned}
$$

Aggregating, we obtain:

$$\dot{W}_t = (r_t - \theta) W_t + (1 - \delta) \left(X_t^U + X_t^{Rn} \right) + \left(1 - \delta^R \right) X_t^{Ro} + g^n V_t^U + g^n N_t^R v_t^{Rn} - I_t$$

Now equate $W = V$ and infer

$$\theta W_t = X_t (1 - \kappa)$$

and the interest rate satisfies

$$
\begin{aligned}
r_t &= \frac{\dot{X}_t}{X_t} + \theta \left[\delta \left(x_t^U + x_t^{Rn} \right) + \delta^R x_t^{Ro} \right] / (1 - \kappa) - \frac{\theta}{1 - \kappa} g^n \frac{V_t^U + N_t^R v_t^{Rn}}{X_t} \\
&= \frac{\dot{X}_t}{X_t} + \theta \left[\delta \left(x_t^U + x_t^{Rn} \right) + \delta^R x_t^{Ro} \right] / (1 - \kappa) - \frac{\theta}{1 - \kappa} g^n \frac{X_t (1 - \kappa) / \theta + N_0^R \left[v_t^{Rn} - v_t^{Ro} \right]}{X_t} \\
&= \frac{\dot{X}_t}{X_t} - g^n + \theta \left[\delta \left(x_t^U + x_t^{Rn} \right) + \delta^R x_t^{Ro} \right] / (1 - \kappa) - \frac{\theta}{1 - \kappa} g^n \frac{N_0^R \left[v_t^{Rn} - v_t^{Ro} \right]}{X_t}
\end{aligned}
$$

As for aggregate output growth, we have

$$\frac{\dot{X}_t}{X_t} = g^n + g^z$$

so that:

$$r_t = g^z + \theta \left[\delta \left(x_t^U + x_t^{Rn} \right) + \delta^R x_t^{Ro} \right] / (1 - \kappa) - \frac{\theta}{1 - \kappa} g^n \frac{N_0^R \left[v_t^{Rn} - v_t^{Ro} \right]}{X_t} \tag{35}$$

The last term makes clear that the interest rate will initially be lower with FDI.

The reason is that $g^n \left(V^U + N_t^R v_t^{Rn} \right) > g^n V_t$ so the asset demand in U increases more when there is FDI. This depresses even more interest rates.

Asymptotically, the last term disappears (since v_t^{Rn} and v_t^{Ro} grow at rate g^z while X grows at rate g) and x_t^{Ro} tends to 0, so that

$$r_\infty = g^z + \frac{\theta \delta}{1 - \kappa} = r_{aut}$$

Since $v_t^{Rn} > v_t^{Ro}$ and $\delta^R x_t^{Ro} \le \delta x_t^{Ro}$, we have:

$$r_t \le r_\infty$$

The solution for the interest rate requires that we feed in a solution for the asset values v_t^{Rn} and v_t^{Ro}. Integrating forward, they satisfy:

$$
\begin{aligned}
v_t^{Ro} &= \delta^R Z_t^R \int_t^\infty e^{- \int_t^s (r_u - g^z) du} ds \\
v_t^{Rn} &= \delta Z_t^R \int_t^\infty e^{- \int_t^s (r_u - g^z) du} ds
\end{aligned}
$$

so that $v_t^{Ro}/v_t^{Rn} = \delta^R/\delta$ and we obtain:

$$r_t = g^z + \frac{\theta}{1-\kappa}\left[\delta\left(x_t^U + x_t^{Rn}\right) + \delta^R x_t^{Ro}\right] - \frac{\theta}{1-\kappa}g^n\frac{V_t^{Ro}}{X_t^{Ro}}x_t^{Ro}\left(\delta/\delta^R - 1\right) \tag{36}$$

where

$$V_t^{Ro} = \delta^R X_t^{Ro}\int_t^\infty e^{-\int_t^s (r_u - g^z)du}ds \tag{37}$$

$$\dot{V}_t^{Ro} = -\delta^R X_t^{Ro} + r_t V_t^{Ro} \tag{38}$$

What complicates the problem is that the equilibrium interest rate depends upon the current value of V_t^{Ro}/X_t^{Ro} which in turn depends upon the entire sequence of future interest rates.

To solve this problem, define $\hat{v}_t^{Ro} = V_t^{Ro}/X_t^{Ro} = v_t^{Ro}/Z_t^R$. It satisfies

$$\frac{d\hat{v}_t^{Ro}}{dt} = (r_t - g^z)\hat{v}_t^{Ro} - \delta^R$$

and the interest rate can be expressed in terms of $\hat{v}_t^{Ro}$ and x_t^{Ro} as:

$$r_t = g^z + \frac{\theta}{1-\kappa}\left[\delta\left(1 - x_t^{Ro}\right) + \delta^R x_t^{Ro}\right] - \frac{\theta}{1-\kappa}g^n\hat{v}_t^{Ro}x_t^{Ro}\left(\delta/\delta^R - 1\right)$$

If we note further that x_t^{Ro} follows simple dynamics:

$$\dot{x}_t^{Ro} = -g^n x_t^{Ro}$$

we obtain a single equation for $\frac{d\hat{v}_t^{Ro}}{dt}$ with a forcing term x_t^{Ro} :

$$\frac{d\hat{v}_t^{Ro}}{dt} = \frac{\theta}{1-\kappa}\left[\delta\left(1 - x_t^{Ro}\right) + \delta^R x_t^{Ro} - g^n\hat{v}_t^{Ro}x_t^{Ro}\left(\delta/\delta^R - 1\right)\right]\hat{v}_t^{Ro} - \delta^R$$

We can solve this differential equation by 'reversing time'. Since $r_t \to r_{aut}$, $\hat{v}_t^{Ro}$ settles to:

$$\hat{v}_\infty^{Ro} = \frac{\delta^R}{\delta}\frac{1}{\theta}$$

We start at $t = \infty$ with x^{Ro} very close to 0 and $\hat{v}^{Ro} = \hat{v}_\infty^{Ro}$ then move 'back' in time until $x^{Ro} = x_0^{Ro}$.

Finally, after we find the solution, we integrate backward the budget constraint to obtain wealth using $w_t^U = W_t^U/X_t^U$ and

$$\begin{aligned}
\dot{w}_t^U &= \frac{\dot{W}_t^U}{X_t^U} - g\,w_t^U \\
&= \frac{(r_t - \theta)W_t^U + (1-\delta)X_t^U + g^n V_t^U + g^n N_t^R v_t^{Rn} - P_t - I_t}{X_t^U} - gw_t^U \\
&= (r_t - \theta - g)w_t^U + \left(1 - \delta - \frac{\kappa}{x_t^U}\right) + g^n\left(\hat{v}_t^U + \frac{N_t^R v_t^{Rn}}{X_t^{Rn}}\frac{x_t^{Rn}}{x_t^U} - \kappa_p\frac{x_t^{Rn}}{x_t^U}\right) \\
&= (r_t - \theta - g)w_t^U + \left(1 - \delta - \frac{\kappa}{x_t^U}\right) + g^n\left(\frac{1-\kappa}{\theta}\frac{1}{x_t^U} - \hat{v}_t^{Ro}\frac{x_t^{Ro}}{x_t^U}\left(1 - \frac{\delta}{\delta^R}\right) - \kappa_p\frac{x_t^{Rn}}{x_t^U}\right)
\end{aligned}$$

where the last line uses:

$$V_t = \frac{1-\kappa}{\theta}\cdot X_t = V_t^U + N_t^R v_t^{Rn} + N_0^R v_t^{Ro}\left(1 - \frac{\delta}{\delta^R}\right)$$

50

A.9 Solving the Model with Exchange Rates

We use a shooting algorithm to solve for the initial terms of trade q_{0+}^i and asset values V_{0+}^i after the shock. Define $w_t = W_t^U / X_t^U$ and $x_t = X_t^U / \sum_i q_t^i X_t^i$. The system (w_t, x_t, q_t^i) satisfies:

$$\dot{w}_t = (r_t - \theta - g)w_t + (1 - \delta) \tag{39}$$

$$1 = \theta \gamma w_t P_t^{U(\sigma-1)} + (1 - \gamma)\left(\frac{1}{x_t} - \theta w_t\right) P_t^{i(\sigma-1)} \tag{40}$$

$$\dot{x}_t = x_t(1 - x_t)\left(g - g^i - \frac{\dot{q}_t^i}{q_t^i}\right) \tag{41}$$

$$r_t = x_t(g + \delta\theta) + (1 - x_t)\left(g^i + \frac{\dot{q}_t^i}{q_t^i} + \delta^i\theta\right) \tag{42}$$

Equation (39) is the wealth dynamics for country i. Equation (40) is the equilibrium condition on the market for good U. Equation (41) characterizes the law of motion of relative output. Unlike the one-good model, the path for future interest rates depends upon the future sequence of terms of trade, which depends upon the current and future asset values.

We start with a guess for the asset values V_{0+}^i immediately after the shock. Given the initial portfolio allocation, we infer the initial wealth distribution W_{0+}^i. We then use (40) to solve for the initial terms of trade q_{0+}. Finally, we integrate (39)-(42) forward to construct the path of future interest rates and terms of trade r_t, q_t consistent with equilibrium on the goods markets. We then use

$$V_{0+}^i = \delta^i \int_0^\infty q_t^i X_t^i e^{-\int_0^s r_u du} ds$$

$$= q_0^i X_0^i \delta^i \int_0^\infty e^{-\theta \int_0^s \bar{\delta}_u du} \frac{x_s^i}{x_0^i} ds$$

to update our guess for V_{0+}^i, where $\bar{\delta}_t = \sum_i x_t^i \delta^i$ is the average (time-varying) capitalization ratio.

B   Non-Ricardian environments

In this appendix, we show how two standard non-Ricardian models – Blanchard's model and Weil's model – generate an aggregate consumption function of the form

$$C_t = \tilde{\theta}(W_t + H_t)$$

where W_t is aggregate tradeable financial wealth in the economy and H_t is the aggregate nontradeable wealth of agents *currently alive*. In those models, $H_t < N_t$ where N_t is the net nontradeable wealth of agents *currently alive and to be born in the future.* The quantity $N_t - H_t$ is then the net non tradeable wealth that cannot be pledged or consumed against by agents currently alive. Our model in the main text is simply one in which $H = 0$, which we show to be a special case of expanded versions of Blanchard (1985) and Weil (1987)'s models.

B.1   Blanchard's model

In this section, we modify the preferences and demographics of our model and adopt the specification in Blanchard (1985).

We keep the production side of our model unaltered: we consider a continuous-time endowment economy, where the aggregate endowment at date t is X_t and grows at rate g. There are two assets in the economy. The first asset can be traded across cohorts. It pays a dividend δX_t every period. The second asset cannot be traded *across cohorts*. It is an *annuity* that pays $z(s,t)$ at time t to an agent born at s.[28] We assume that the aggregate income from that nontraded asset equals $(1-\delta)X_t$ at time t:

$$\int_{-\infty}^{t} z(s,t)\, pe^{-p(t-s)} ds = (1-\delta)X_t$$

where p represents each agent's constant probability of death p. At any instant in time, a new cohort whose size is normalized to p is born. There is a competitive life-insurance sector: agents may contract to make or receive payments contingent on their death. In the absence of a bequest motive, and if negative bequests are prohibited, agents with *tradeable* wealth w enter in a contract which transfers their tradeable wealth to the insurance company contingent on their death. In equilibrium, contracts are actuarially fair: a contract pays w to the insurance companies if the agent dies, and pays the agent pw if he lives.

As in Blanchard, we assume that utility is logarithmic with discount factor $\tilde{\theta}$. Under these conditions, aggregate consumption is given by

$$C_t = (p+\tilde{\theta})(W_t + H_t)$$

where H_t represents the aggregate nontradeable wealth of agents *currently alive*. If we define $h(s,t)$ the time-t value of the annuity for an agent born at time $s < t$, and $R(t,z) = \exp\left[-\int_t^z (r_u + p)\, du\right]$ the discount factor between time t and time $z \geq t$, we obtain:

$$
\begin{aligned}
h(s,t) &= \int_t^\infty z(s,u)\, R(t,u)\, du \\
H_t &= \int_{-\infty}^t h(s,t)\, p\, e^{-p(t-s)} ds
\end{aligned}
$$

Aggregate (financial) wealth W_t evolves according to

$$\dot{W}_t = r_t W_t + (1-\delta)X_t - (p+\tilde{\theta})(W_t + H_t) \tag{43}$$

The value of the tradeable asset, V_t, evolves according to:

$$r_t V_t = \dot{V}_t + \delta X_t$$

and the asset market clears if and only if $W_t = V_t$.

The only difference between this model and the model in the main text is the presence of the term H_t on the right hand side of (43). The determination of nontradable wealth H_t depends on how the aggregate income from the nontradeable asset $(1-\delta)X_t$ is distributed.

---

[28]This is equivalent to a set-up with one asset, but where only the fraction δX_t can be capitalized and traded across cohorts.

We first consider the case where $(1 - \delta)X_t$ is distributed over time, as in Blanchard (representing labor income in his case). In that case, H_t evolves according to:

$$\dot{H}_t = (r_t + p) H_t - (1 - \delta) X_t$$

while the evolution of N_t is:

$$\dot{N}_t = r_t N_t - (1 - \delta) X_t.$$

These two expression differ as long as $p > 0$, and it follows from them that in this case $N > H$ throughout.

Finally, we consider the case where $(1 - \delta)X_t$ is given as an initial endowment to agents born at date t. In that case, nontradeable wealth H_t is zero (while N_t remains unchanged), and we recover exactly the same differential equations for aggregate wealth as in the model in the main text if we replace θ in the main text in place of $p + \tilde{\theta}$, the effective discount rate.

$$
\begin{aligned}
\dot{W}_t &= (r_t - \theta) W_t + (1 - \delta)X_t \\
C_t &= \theta W_t
\end{aligned}
$$

B.2 Weil's model

It is important to realize that what matters is that $N > H$, *not* that agents have a finite horizon. This point can be highlighted with Weil (1987) model. In this model, population size grows at rate n_t. Agents of each generation are infinitely-lived log-utility consumers.

Let us keep the production side of our model unaltered: we consider a continuous-time endowment economy, where the endowment at date t is X_t. There are two assets in the economy. The first asset can be traded across cohorts. It pays a dividend δX_t every period. The second asset cannot be traded across cohorts. It is an *annuity* that pays $z(s, t) e^{-\int_{-\infty}^{s} n_u du}$ at time t to an agent born at time s. We assume that the aggregate income from that nontraded asset equals $(1 - \delta) X_t$ at time t:

$$\int_{-\infty}^{t} z(s, t)\, ds = (1 - \delta) X_t$$

Agents can trade shares in the tradable asset. The endowment grows at rate g.

Weil shows that aggregate consumption is given by

$$C_t = \tilde{\theta}(W_t + H_t)$$

where W_t is tradeable financial wealth and H_t measures non-tradeable wealth. Aggregate wealth W_t evolves according to

$$\dot{W}_t = r_t W_t + (1 - \delta)X_t - \tilde{\theta}(W_t + H_t) \tag{44}$$

The value of assets V_t evolves according to

$$r_t V_t = \dot{V}_t + \delta X_t$$

53

and the asset market clears if and only if $W_t = V_t$.

The only difference between Weil's model and the model in the main text is the presence of non tradeable wealth H_t on the right hand side of (44). The determination of H_t depends on the way the aggregate annuity income $(1 - \delta) X_t$ is distributed.

As Blanchard, Weil considers the case where $(1 - \delta)X_t$ is split equally among agents. In that case, aggregate nontradable wealth H_t evolves according to

$$h(s,t) = \int_t^\infty z(s,u) R(t,u) \, du$$

$$H_t = \int_{-\infty}^t h(s,t) \, ds$$

where $R(t,z) = \exp\left[-\int_t^z r_u du\right]$. We obtain:

$$H_t = \int_t^\infty (1 - \delta) X_u \exp\left[-\int_t^u n_v dv\right] R(t,u) \, du$$

$$\dot{H}_t = (r_t + n_t) H_t - (1 - \delta) X_t$$

Again, this contrasts with the corresponding expressions for N_t:

$$N_t = \int_t^\infty (1 - \delta) X_u R(t,u) \, du$$

$$\dot{N}_t = r_t N_t - (1 - \delta) X_t$$

It is apparent that $N_t > H_t$ as long as $n > 0$.

Alternatively, we can consider the case where $(1 - \delta)X_t$ is given exclusively as an initial endowment to agents born at date t. In that case, non tradeable wealth H_t is zero, and we recover exactly the same differential equations for aggregate wealth as in the model in the main text (with $\tilde{\theta} = \theta$)

$$\dot{W}_t = \left(r_t - \tilde{\theta}\right) W_t + (1 - \delta)X_t$$

B.3 The Meltzer Diagram

B.3.1 Blanchard's model

Consider the Blanchard model summarized above, assuming that non-tradeable asset income $(1 - \delta)X_t$ is distributed across agents as a flow. Imagine a small open economy growing at rate g and facing a constant interest rate $g + p + \tilde{\theta} > r > g + \tilde{\theta}$. On the balanced growth path:

$$\lim_{t\to\infty} \frac{W_t}{X_t} = \frac{\left(r - g - \tilde{\theta}\right)(1 - \delta)}{(p + r - g)(p + \tilde{\theta} + g - r)} \tag{45}$$

$$\frac{V_t}{X_t} = \frac{\delta}{r - g} \tag{46}$$

$$\frac{H_t}{X_t} = \frac{1 - \delta}{r + p - g}$$

$$\frac{N_t}{X_t} = \frac{1 - \delta}{r - g}$$

The asset demand curve (45) is increasing in r and decreasing in δ. While the expression for the interest rate has no closed form solution in this case, the conclusions are qualitatively similar to the ones we stress as long as $p > 0$.[29]

The asset supply curve (46) is decreasing in r and increasing in δ. Since for a given interest rate, V_t/X_t goes up with δ, this implies that the autarky interest rate defined implicitly in the following equation is increasing in δ :

$$\frac{(r_{aut} - g)\left(r_{aut} - g - \tilde{\theta}\right)}{(p + r_{aut} - g)(p + \tilde{\theta} + g - r_{aut})} = \frac{\delta}{1 - \delta}$$

For $r \neq r_{aut}$, we can express the current account deficit on the balanced growth path:

$$\frac{CA_t}{X_t} = g\left[\frac{\left(r - g - \tilde{\theta}\right)(1 - \delta)}{(p + r - g)(p + \tilde{\theta} + g - r)} - \frac{\delta}{r - g}\right]$$

Hence we can perform a Metzler diagram analysis as in the main text of the paper: the current account is increasing in r, and decreasing in δ.

What is novel is that we can now distinguish between the role of $\tilde{\theta}$ and p. The asset supply curve is invariant with respect to these parameters. The asset demand curve is decreasing in p and in $\tilde{\theta}$. Hence a shortening of the time horizon or a higher discount rate are forces for a current account deficit.

B.3.2 Weil's model

Consider the Weil model summarized above, assuming that non tradable asset income $(1-\delta)X_t$ is distributed as a flow over time. Imagine a small open economy growing at rate g and facing a constant interest rate r, such that $r + n > g + \tilde{\theta} > r > g$. Then, on the balanced growth path,

$$\lim_{t \to \infty} \frac{W_t}{X_t} = \frac{r + n - g - \tilde{\theta}}{g + \tilde{\theta} - r} \frac{(1 - \delta)}{r + n - g}$$

$$\frac{V_t}{X_t} = \frac{\delta}{r - g}$$

$$\frac{H_t}{X_t} = \frac{1 - \delta}{r + n - g}$$

$$\frac{N_t}{X_t} = \frac{1 - \delta}{r - g}$$

As above, the asset supply curve is decreasing in r and increasing in δ, while the asset demand curve is increasing in r and decreasing in δ. The latter is again a consequence of the non-Ricardian feature of this environment.

The asset market clears if and only if r is given by:

$$\frac{n - (g + \tilde{\theta} - r_{aut})}{g + \tilde{\theta} - r_{aut}} \frac{r_{aut} - g}{r_{aut} - g + n} = \frac{\delta}{1 - \delta}$$

---

[29]Note that $p > 0$ captures the non-Ricardian feature of this model. When p converges to zero, r converges to $g + \tilde{\theta}$ and no longer depends on δ.

When $n = 0$, we find the usual condition $r = g + \tilde{\theta}$. With $n > 0$, r depends positively on δ.

The current account is given by:

$$\frac{CA_t}{X_t} = g \left[\frac{r + n - g - \tilde{\theta}}{g + \tilde{\theta} - r} \frac{(1 - \delta)}{r + n - g} - \frac{\delta}{r - g} \right]$$

Hence we can perform a Metzler diagram analysis as in the main text of the paper: the current account is increasing in r, and decreasing in δ.

C "Calibration"

This section discusses the choice of parameters underlying Figures 3-10. The 'calibration' of the model requires parameter values for δ, θ, g, x_0, α_0^{iU}, α_0^{Ui}, $(g - g^E)$ and $(\delta - \delta^R)$. We chose to assign parameters approximately based on US aggregate data. Table 1 summarizes our parameter assumptions.

Parameter	θ	g	δ	x_0^E	x_0^R	μ_{0-}^{iU}	NA_{0-}^U/X_0^U	$\frac{\Delta V^R}{V^R}\big|_{t=0}$	$(g - g^E)$	$(\delta - \delta^R)$
Value	0.25	3%	0.12	0.5	0.3	0.05	0	-0.5	1.11%	0.07

Table 1: Main Parameters

According to (4), we should think of θ as the output to financial wealth ratio, X/W. We obtain an estimate of W as the net financial worth of the household sector. According to the US Flow of Funds, it is equal to \$48.52 trillion in 2004.[30] With a US GDP of \$11.73 trillion in 2004, this implies $\theta = \frac{11.73}{48.53} \sim 0.24$. In the simulations, we round this parameter to 0.25. Average output growth in the U.S. between 1950 and 2004 equals 3.33%. We round this number and set the growth rate g to 3 percent. Finally, we assume a value of r_{aut} equal to 6%. This implies a value of δ of $(r - g)/\theta = 0.12$. [31]

We now turn to the output shares. We define U as the U.S., the U.K. and Australia. These countries are good asset suppliers, and experienced robust growth in the past decade. We identify E with developed non-oil producing countries with sound financial markets, but a lackluster growth performance. Accordingly, we define E as countries from the European Union (less the UK), Iceland, Japan, New Zealand, and Switzerland. Finally, we identify R with developing and oil producing countries with a good income growth potential, but limited asset production capacity.[32]

---

[30] See the Balance Sheet Table B100, line 42 of the September 2005 release.

[31] Another possible way to calibrate δ is to observe that in steady state, the P/E ratio is $V/\delta X = 1/\delta\theta$. The P/E ratio for the S&P 500 averages 18.2 for the period 1950-2005.(see Robert Shiller's webpage at http://www.econ.yale.edu/~shiller/data.htm).) This yields $\delta = 0.22$,. This value of δ would imply a risk free rate of 8% which we view as too high. Since not all assets in the economy are capitalizable, we prefer our estimate of δ.

[32] The list includes Argentina, Brazil, Chile, China, Colombia, Costa Rica, Ecuador, Egypt, Hong-Kong, India, Indonesia, Korea, Mexico, Malaysia, Nigeria, Panama, Peru, Philippines, Poland, Russia, Singapore, Thailand and Venezuela. Output data for Poland and Russia starts in 1990.

We measure the initial output share as the average output share between 1980 and 2003.[33] We find

$$x_0^E = \frac{X_0^E}{X_0^E + X_0^U} \approx 0.50$$

$$x_0^R = \frac{X_0^R}{X_0^R + X_0^U} \approx 0.30.$$

Lastly, we assume that the initial portfolio share for U-trees equals the share of US assets in ROW financial wealth, as estimated in figure 1(c). We adopt an initial value of 0.05. Figure 1(c) is constructed as the ratio of US gross external liabilities (from the BEA's US International Investment Position) to the Rest of the World's financial wealth. To estimate the latter, we calculate the ratio of financial wealth to output for the US, the EU and Japan between 1982 and 2004.[34] We find a GDP weighted average of 2.48. We apply this ratio to the Rest of the World GDP. For 2004, we estimate a financial wealth of \$72 trillion for the ROW and \$36 trillion for the US.

We set:

$$\mu_{0-}^{iU} = \frac{\alpha_0^{iU} V_{0-}^U}{W_{0-}^i} = 0.05 \tag{47}$$

where $i \in \{E, R\}$. Furthermore, we assume that the initial net foreign asset position is 0.[35] This implies that

$$V_{0-}^i = W_{0-}^i = \frac{X_0^i}{\theta}.$$

Substituting into (47), we obtain

$$\alpha_0^{iU} = \mu_{0-}^{iU} \frac{x_0^i}{1 - x_0^i}$$

which yields:

$$\alpha_0^{EU} = 0.05$$

$$\alpha_0^{RU} = 0.02.$$

Finally, since

$$W_{0-}^U - V_{0-}^U = \alpha_0^{Ui} V_{0-}^i - \alpha_0^{iU} V_{0-}^U = 0$$

we find

$$\alpha_0^{Ui} = \mu_{0-}^{iU} = 0.05$$

We now describe the parameters for our shocks. We set the decline in E's growth rate, $(g - g^R) = 1.11\%$. According to the WDI, E's average growth rate between 1980 and 1992 was 2.73% and only 1.63% between 1992 and 2003 (ppp-adjusted).

---

[33] We use GDP data in current dollars from the World Development Indicators.

[34] Sources: US: Flow of Funds, Table B100 line 8, household financial assets; EU: Table 3.1 of the ECB Bulletin, financial and capital account of the non financial sector; Japan: Flow of Funds, households total financial assets, available at http://www.boj.or.jp/en/stat/stat_f.htm.

[35] According to the Bureau of Economic Analysis, the US had a zero net foreign asset position in 1988.

We calibrate the decline in δ^R so that it matches the decline in asset values around the time of the Asian crisis. From Section 2.3, R's assets price drops from $V_{0-}^R = X_0^R/\theta$ before the shock to $V_{0+}^R = \delta^R/\theta\bar{\delta}X_0^R$ where $\bar{\delta} = \left(x_0^U\delta + \left(1 - x_0^U\right)\delta^R\right)$ is the world capitalization index. Hence the drop in asset values at $t = 0$ is

$$\frac{\Delta V^R}{V^R}|_{t=0} = \delta^R/\bar{\delta} - 1 < 0.$$

Solving this expression for δ^R, we obtain

$$(\delta - \delta^R) = \delta\left(1 + \frac{x_0^U\left[1 + \frac{\Delta V^R}{V^R}|_{t=0}\right]}{\left[\frac{\Delta V^R}{V^R}|_{t=0}\left(1 - x_0^U\right) - x_0^U\right]}\right).$$

The decline in dollar asset values was 37 percent in Hong-Kong, 75 percent in Korea and 83 percent in Indonesia.[36] We conservatively consider a decline of 50 percent. This implies:

$$(\delta - \delta^R) = 0.07;\ \delta^R = 0.05$$

---

[36]We calculated the decline between July 1997 and January 1998 of the Hang Sen Composite Index (Hong Kong), the KOSPI (Korea) and the Jakarta Stock Index (Indonesia). All price indices were converted into dollars using daily exchange rates.
