Conference on Economics of Payments IX

16 November 2018

Any views expressed are solely those of the authors and so cannot be taken to represent those of the Bank of England or to state Bank of England policy. This presentation should therefore not be reported as representing the views of the Bank of England or members of the Monetary Policy Committee, Financial Policy Committee, Prudential Regulation Committee or any other institution with which the authors may be affiliated or associated.

Outline

- Motivation
- Research Question
- Literature
- Data & Network Construction
- PageRank and Eigenvector Centrality

- VM Shock and Contagion Model
- Comparison of different rankings
- Conclusions and Future Work

1.0 Motivation

1.1 Motivation

- The impact of VM shocks on financial markets is important for regulatory authorities.
- OTC derivatives can threaten financial stability through asymmetric and off-balance sheet exposures.
- Contagion does not require the default of an institution. Delayed payments can create liquidity stress.

What is the most efficient centrality measure?

1.2 What We Do

- We use Trade Repository data to construct the multi-layered network of exposures in the IR, CD, and FX markets.
- We propose a PageRank centrality measure to rank the most important institutions in our network, and we compare it with the eigenvector centrality measure.
- Then we test the potential for liquidity contagion after a VM shock.
 - For each firm we estimate the stress they produce (and receive) under a generic shock.
 - We compare the rankings obtained by using different centrality measures with the ranking of deficiencies obtained by using our contagion algorithm.

- El-Omari et al. (2018); Fiedor et al. (2017)

2.1 Data

- The Trade Repository data consists of reported transactions of derivatives when:
 - All transactions are through UK CCPs.
 - One of the counterparties is UK-domiciled.
 - For CDSs, either one of the counterparties and/or the underlying is UK-domiciled.
 - Contracts are sterling denominated.
- We use all open positions reported to DTCC and Unavista TRs on 30th June 2016.
- We focus only on the clearing members' transactions (centrally and non-centrally cleared).

2.2 Network Construction

- IR transactions dominate the cleared market, followed by CD transactions.
- Very few FX contracts are centrally cleared

Fraction of centrally and non-centrally cleared transactions:

	Cleared	Uncleared
IR	68.69%	31.31%
CD	8.47%	91.53%
FX	0.92%	99.08%

Summary statistics:

	Notional	# trades	Cleared notional
IR	2.64E+14	3,674,857	2.10E+14
CD	1.10E+14	1,033,158	2.87E+12
FX	6.90E+13	5,975,179	3.26E+12

2.3 Structural Properties and Correlation

$N_{lay}^{[IR]}$	$N_{lay}^{[CD]}$	$N_{lay}^{[FX]}$
473	1469	553
$\delta(a=1)$	$\delta(a=2)$	$\delta(a=3)$
0.893	0.066	0.041

	IR	CD	FX
IR	1.00	-0.24(4)	0.14(3)
CD	-0.24(4)	1.00	-0.36(5)
FX	0.14(3)	-0.36(5)	1.00

3.1 PageRank Centrality

 Understanding the vulnerability of the system to failure by using the PageRank centrality measure.

(日)、

э

3.2 PageRank Centrality (cont'd)

4.0 VM Shock Estimation

- We use the same shock evaluation method used in Heath et.al. (2016).
- We define Δp as the change in the price of product k since the last variation margin payment (assumed to be normally distributed around zero).
- Then next variation margin payment is given by $VM_{ij}^{K} = E_{ij}^{K}\Delta p$.
- For participants *i* and *j*, the random variable for variation margin obligations over the margining period is VM^K_{ij} ~ N(0, σ²_{E_{ij}} E²_{ij}), where σ²_{E_{ij}} = e'Ωe.

4.1 Contagion Model

- The seminal paper by Eisenberg and Noe (2001) shows how to compute clearing payments in a network of obligations.
 - If my counterparties do not pay back their obligations in full to me, in turn I might not be able to make good on all my payments.

- The vector of realised payments is the fixed point of a set of equations that can be computed iteratively.
- In order to study the network of CDSs, we extend the work of Paddrik et al. (2016):
 - To consider a multiplex network
 - To analyze a liquidity shock.

4.2 One Layer: Paddrik et al. (2016)

- First step: Each firm computes the maximum potential liquidity stress that it will transmit to its counterparties, i.e. its obligations minus its incoming payments.
 - CCPs will use their cash or other cash equivalents to absorb (part of) the stress.
- Second step: Liquidity buffers for each firm are difficult to calibrate.

 Third step: Each firm computes the deficiency in its payments (payments are computed pro-rata).

4.3 Transmission Factor

 Aggregate VM payments that institutions are requested to make (purple dashed line) and aggregate deficiencies in those VM payments (blue solid line) as a function of the transmission factor τ, both expressed in US billion dollars.

4.4 Transmission Factor (cont'd)

Deficiencies in VM payments broken down by layer as a function of the transmission factor \(\tau\). Blue solid lines refer to US billion dollar aggregate deficiencies, orange dashed lines refer to US billion dollar deficiencies of CCPs only.

◆□▶ ◆□▶ ◆臣▶ ◆臣▶ ─臣 ─のへで

4.5 Shock Size

 Aggregate deficiencies in VM payments expressed in US billion dollars as a function of the shock factor β, for different values of τ.

4.6 Contributions to Deficiencies

 Top 250 individual institutions contributing to deficiencies (left panel) and experiencing deficiencies (right panel) in VM payments expressed in US million dollars.

5.1 Conclusions and Future Work

- We find that, for \(\tau\) between 0.5 and 1, between 0.3% and 0.6% of institutions experience materially large deficiencies, while between 0.5% and 1.2% of institutions give material contributions to the aggregate deficiency.
- We show that the rankings of vulnerability based on the Abs FMP centrality correlate reasonably well with rankings based on deficiencies computed via the contagion algorithm. This suggests that the Abs FMP centrality could be used as a proxy for calculating the potential vulnerability of institutions.
- ► The framework could be very useful to study solvency contagion risk.
- A possible future extension of our work could be to tie VM shocks to specific macroeconomic shocks.

5.2 Conclusions and Future Work (cont'd)

- Aggregate liquidity need = £33bn (vs. average daily cash borrowing in global repo markets of > £0.5tr).
- Aggregate liquidity need = £6bn if all (scaled down) liquid assets were used to pay margins.
- Aggregate liquidity need = £0 if all (non-scaled down) liquid assets were used to pay margins.
