Disentangling the supply and demand factors of household credit in Malaysia: evidence from the credit register

Soh Jiaming ¹

Abstract

This paper isolates the demand and supply factors of credit extension. We construct a new dataset that combines loan application information from the credit register with individuals' income and banks' balance sheet for the period 2014-2016. Using this dataset, we verify the importance of banks' balance sheet (supply factor) and individuals' income (demand factor) in determining housing and car loan approval empirically. We have two main findings. First, we find that banks' balance sheet matters. Banks with a higher funding ratio, higher capital ratio, and lower liquidity ratio are more likely to approve a housing and car loan. Among the supply factors, the funding ratio of the banks is the strongest determinant of household lending. Second, we find that the supply factors have a greater impact on household loan approval than the demand factor. Specifically, the effect of banks' funding ratio on loan approval is twice the size of income. Therefore, the declining funding ratio due to higher net external outflows may potentially explain the moderation in aggregate household loan approval growth in 2014-2016. The findings fill a research gap for the Malaysian economy and could serve to inform policies, especially in relation to the discussion on the role of banks' balance sheet in lending activities.

Keywords: Supply factor, demand factor, household loan approval, credit register, funding ratio

1. Introduction

To what extent do individuals' and banks' balance sheet affect credit extension? A complete understanding of their respective roles requires the separation of the two. In this paper, we attempt to isolate the demand and supply factors of credit. A better understanding of the drivers of credit is essential to inform appropriate policy responses. For example, if slow credit growth is explained mainly by weak credit demand, economic policies aimed at expanding aggregate demand would be more appropriate. On the other hand, if credit growth is driven by weak banks' balance sheet, policies would need to focus on improving the financial health of banks to increase their willingness to lend².

However, to disentangle the two factors is an inherently difficult task. Most of the studies overcame this difficulty by relying on the rich micro-level dataset from the credit register (Khwaja and Mian (2008), Jimenez et al. (2017) and Schepens et al. (2018)). Therefore, this paper aims to provide new findings by using a novel micro-level dataset to trace how supply and demand factors affect household loan approval in Malaysia.

The main contribution of this paper is twofold. First, we create a novel borrower-bank pair dataset that links the loan application information to individuals' income and banks' balance sheet. Second, to our knowledge, this is among the first few papers that quantify and assess the relative role of supply and demand factors of credit for an emerging country in Asia³.

For the first contribution, we match three primary official data sources to create the borrower-bank pair dataset. The data sources are 1) a credit register database that contains the universe of loan application information, 2) an income tax database that includes the borrowers' profile and income information and 3) a banking database that contains detailed information on banks' balance sheet. However, at this juncture information from the income-tax database is only available for the period 2014-2016. In addition, only individuals who filed the income tax return forms *and* applied for loans will be included in our dataset.

For the second contribution, using the borrower-bank dataset, we identify the respective roles of demand and supply factors in determining the probability of household loan approval. The demand factor is proxied using borrowers' income. The supply factors are proxied using banks' capital ratio, funding ratio, and liquidity ratio.

Utilising two different empirical methods (more details in Section 4), we regress the credit application status on a set of individual-time fixed effect and bank-varying supply-side controls. We have two main findings. First, banks' balance sheet matters. Banks with a higher funding ratio, higher capital ratio and lower liquidity ratio are more likely to lend. Among the supply factors, the funding ratio is the strongest determinant of household lending. Second, we find that the supply factors have a greater impact on household loan approval than the demand factor. Specifically, the effect of banks' funding ratio on loan approval is twice the size of income. This result highlights the importance of the funding ratio in determining household loan

² Everaert et al. (2015).

³ Jimenez et al. (2017) studied Spain, Khwaja and Mian (2008) studied Pakistan and Schepens et al. (2018) studied Belgium.

approval. A declining funding ratio due to high net external outflows can potentially explain the moderation in aggregate household loan approval growth in 2014-2016.

Our study could therefore serve as a starting point for discussions on the impact of policies on banks' balance sheet and ultimately lending activities. In particular, our empirical findings on the importance of banks' funding ratio in credit extension highlight the importance of promoting diversification of the sources of funding for financial institutions, which can help reduce the sensitivity of lending activities to movements in deposit.

The paper will proceed as follow. Section 2 describes the literature review on the demand and supply factors of credit. Section 3 details the creation of a borrower-bank pair dataset. Section 4 elaborates the two identification strategies that we utilise to disentangle the demand and the supply factors. Section 5 presents the results. Section 6 discusses the policy implications and the limitations of results, and finally, Section 7 concludes.

2. Literature review

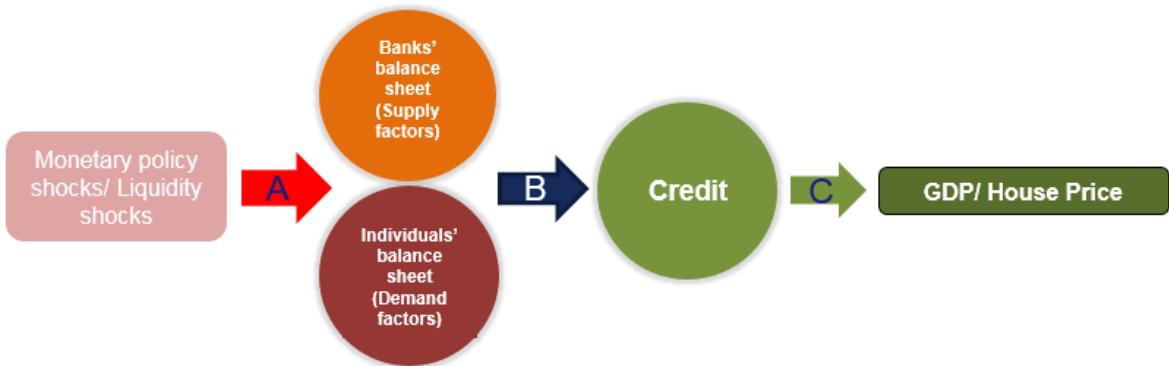

The importance of demand factors such as borrowers' profile and income in getting loan approvals is well accepted, but the role of banks' balance sheet on lending is less studied in Malaysia. Early efforts to disentangle the demand and supply factors of credit was done by Kashyap et al. (1993; 2000). They found that banks' balance sheet matters in monetary policy transmission and the impact of monetary policy on lending is stronger for banks with less liquid balance sheet.

In a more recent paper by Khwaja and Mian (2008), they investigated the impact of liquidity shocks on banks' balance sheet and lending. They found that for the same firm borrowing from two different banks, the loan extended by the bank that experienced a larger decline in liquidity dropped significantly. This provides further evidence on the importance of the supply factors of credit. The studies described above can be summarised as arrow A and arrow B in Chart 1.

Understanding the roles of demand and supply factors of credit goes beyond unravelling the mechanics of credit creation. They do have different impacts on the real economy (arrow C in Chart 1). For example, Mian and Sufi (2017) describes a credit supply expansion as the increase in the quantity of credit or a decrease in the interest rate on credit for reasons unrelated to changes in income or productivity of the borrowers. They found that expansion in credit supply is an important source of business cycle fluctuations and is often associated with a larger growth in loans to households and a larger growth in house prices⁴, with a subsequent deep recession when the credit supply shock reverts.

Therefore, the focus of this study is to first understand the drivers of credit (arrow B). We will leave the investigation of arrow A and C for future research.

⁴ Favara and Imbs (2014) found similar result for house price.

3. The borrower-bank pair dataset

The availability of a rich micro-level dataset is crucial for our analysis. To create a borrower-bank pair dataset, we use three primary official data sources that are housed at the Central Bank of Malaysia. The three data sources include 1) the credit register database containing the universe of individual-level loan applications information, 2) an income tax database containing individual-level gross income information, and 3) a supervisory bank-level database containing banks' balance sheet information.

The credit register

The credit register is collected by the Central Bank of Malaysia to monitor the lending activities of banks. Information in the credit register includes lenders, status of loan application (accepted or rejected), the purpose of loan application, the application amount and the collateral value for housing loan. It has monthly information on the universe of all household loan application in Malaysia. For the purpose of our analysis, we remove joint borrowers. Each loan application is linked to only one borrower's characteristics. We restrict our borrowers to residents only. In this paper, we focus only on housing and car loan applications given that they constitute the majority of household loan⁵. Only new loan applications are considered. Applications for renewal of existing loans are not considered in our analysis.

The credit register has information on borrowers' characteristics such as age, location of residence and employment. Unfortunately, we do not have information on the risk profile of the borrowers (for example, credit score) in the dataset. Also, the income of the borrowers - which is an important demand indicator that we need for

⁵ Housing and car loans comprise 66% of total household loan approval in the 2014-2016 period.

our analysis - is not available in the credit register. Therefore, we rely on the income tax database to fill this missing gap.

The income tax database

We use the income tax database to extract individual-level gross income. This information, however, is only available for those who submitted their income tax return forms in Malaysia. In addition, the income tax database has information on age, gender, location of residence, and marital status. For borrowers' characteristics that are not available from the credit register, we fill the missing information from the income tax database. This provides us with the most comprehensive list of characteristics and loan application information for the borrowers.

Unfortunately, due to the data constraint at this juncture, we only have the 2014-2016 data available in the income tax database. We also do not have information on individuals' wealth or assets.

The bank-level database

The final dataset we use is the monthly banks' balance sheet data collected by the Central Bank of Malaysia. We use banks' capital ratio, funding ratio, liquidity ratio, and size to proxy for the supply factors⁶. The following is the definition for the banks' balance sheet indicators that we use in this paper:

- 1) *Capital ratio* is defined to be the ratio of tier 1 capital⁷ over risk-weighted assets⁸. It measures how much additional buffer a bank has to meet claims in the event of insolvency. We use this to proxy for the financial soundness of banks.
- 2) *Funding ratio* is defined to be the ratio of deposit⁹ over total liabilities. We use this to proxy for funding availability of banks as deposit constitutes the main supply of loanable funds in Malaysia and may act as the driving force of bank lending.
- 3) *Liquidity ratio* is defined to be the ratio of liquid assets¹⁰ over total assets. We use this indicator to represent the available stock of liquid assets to cover unexpected cash outflows and liquidity shocks (for example, unpredictable deposit withdrawal or unpaid credit). Since liquidity comes at a cost, a bank faces a trade-off between the safety of greater liquidity and the expense of obtaining it.
- 4) *Size* is defined as log total assets.

⁶ We restrict our sample to commercial and Islamic banks only.

⁷ Tier 1 capital consists of ordinary share capital, retained earnings and reserve fund.

⁸ Assets include cash, deposit with the Central Bank and other banks, government debt, debt securities and loans extended to the private sector.

⁹ We exclude deposit that are placed by banks.

¹⁰ Liquid assets is defined as the sum of cash, deposit placed at other banks, financial assets and reverse repurchase.

Finally, using a unique identifier for banks and borrowers, we create a borrower-bank pair dataset that links loan application information to individuals' and banks' balance sheet. Note that there will be more loan applications than the number of borrowers since one borrower can apply to multiple banks. Our final sample consists of 530,000 borrowers and 47 banks, with approximately 1.5 million data points over 2014-2016. Chart 2 below summarises the process of creating the borrower-bank pair dataset for Malaysia.

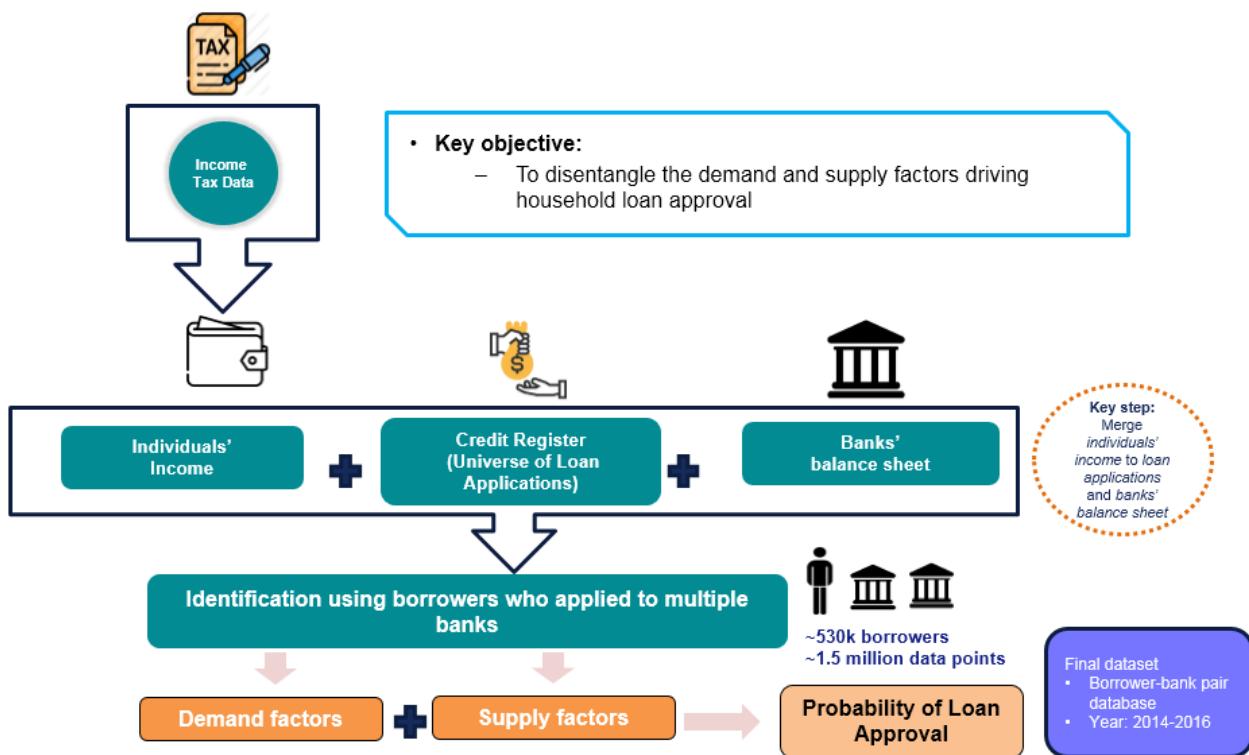

The demand factors are proxied mainly by borrowers' income and other characteristics that could affect the demand for loans. This includes age, occupation, location of residence and marital status. We utilised all the available borrowers' characteristics in the dataset. Supply factors are proxied by banks' capital ratio, funding ratio and liquidity ratio as they indicate banks' capacity and willingness to lend. All relevant demand and supply indicators are standardised in the regression for ease of direct comparison.

It is important to note that since we rely on information that are available from all three data sources, this study only covers individuals who filed the income tax return forms and applied for loans. In addition, many banks in Malaysia pre-filter the loan applications by income before registering the eligible applicants in the credit register. This could potentially induce a sample selection bias as we do not observe individuals from the lower income group, especially those who did not submit any loan applications given their lower probability of obtaining an approval. In fact, individuals in our sample may consist of those with relatively high income in the population.

Table 1 in the Appendix presents the summary statistics for the borrowers' and banks' characteristics. For banks' characteristics, the average funding ratio in the sample is 75%, and the average capital and liquidity ratio is around 10%. Note that compared to other supply factors, the standard deviation for the funding ratio is relatively high, suggesting a significant disparity in the funding ratio across banks in Malaysia.

For borrowers' characteristics, the average monthly gross income is RM 8,600. This confirms our previous claim that individuals in our dataset are relatively well off in the population. The mean income in our dataset is roughly 3 times the average monthly salaries and wages in the population¹¹. On average, the borrowers in our dataset applied to 4 banks and the majority of the loan applications are accepted (~80%).

¹¹ The average monthly salaries and wages in the population is around RM 2500 in 2016. We do not observe the average gross income for the population. Source: Salaries and Wages Survey Report 2016, Department of Statistics Malaysia.

4. Empirical Methodologies

This section outlines the econometric models that we use to overcome the classical identification problem of separating the demand and supply factors of lending. We rely mainly on two methods: the first from Khwaja and Mian (2008), and the second from Schepens et al. (2018). Chart 3 summarises the two methods (Equation 1 and Equation 2) described below.

4.1 Method 1

The first method originates from Khwaja and Mian (2008). We use the sample of borrowers who applied to multiple banks for identification. Intuitively, since the comparison is across banks for the *same* individual, any difference in the loan approvals is arguably due to heterogeneity in banks' balance sheet. Specifically, we regress individual-bank level credit application status on a set of individual-time fixed effect and bank-varying supply controls as shown in Equation 1:

$$Prob(Loan Approval)_{i,j,t} = \beta_i + \boldsymbol{\beta}_1 S_{j,t=1} + \boldsymbol{\beta}_2 X_{i,j,t} + \beta_3 Z_t + \varepsilon_{i,j,t} \quad (1)$$

where i refers to individual i who applied to multiple banks, j refers to bank j, and t refers to time.

We use a linear probability model for the estimation. The key dependent variable is a dummy to indicate the status of the loan application made by individual i to bank j at time t (1 if loan application is approved, 0 otherwise). In this study, we only focus on the quantity of loans as our dependent variable due to the lack of data for the price of loans (i.e. effective interest rate).

β_i refers to individual-fixed effect. Since the comparison is across banks for the same individual i, individual-specific demand factors such as income, age, occupation, location of residence and marital status will be absorbed by the individual fixed effect β_i .

The key independent variable is the vector $S_{j,t=1}$. It consists of bank j's funding ratio, capital ratio, liquidity ratio at time t=1. All these supply factors are estimated simultaneously in one regression¹². We use the supply factors at the beginning of the year to proxy for banks' initial position. This is to reduce the potential reverse causality from loan to deposit. All standard errors are clustered at individual-time level.

Some controls are capture in the vector $X_{i,j,t}$. It includes the amount applied by the borrower, the collateral value¹³, and the banks' size and market share¹⁴. Z_t refers to the time fixed effect to capture macroeconomic shocks during the year. The loan applications must also be submitted in the same year for the same purpose.

However, there are two setbacks in using Equation 1. First, we can only estimate the fixed effect coefficient β_i in the sample of individuals who submitted their loan applications to multiple banks. This will omit individuals who applied to only one bank. Even though the majority of the loan applicants in our dataset (85%) applied to multiple banks, excluding a subset of individuals from the analysis may potentially induce a sample selection problem. Second, under Equation 1 the role of income will be absorbed by the individual-time fixed effect and we will not be able to compare the relative strength of demand and supply factors. Therefore, we rely on an alternative methodology used in Jimenez et al. (2017) and Schepens et al. (2018).

4.2 Method 2

Under this method, instead of using the individual-time fixed effect, we replace it with industry-location-age-marital-time fixed effect. Because we directly observe the borrowers' characteristics in the dataset, we do not have to rely on the individual fixed-effect. The benefits of this approach is two-fold. First, it allows us to include all borrowers in our analysis. Second, since the income effect is not absorbed, we can compare the size of the coefficient for the demand factor (proxied by income) and supply factors (proxied by banks' characteristics) to assess their relative strength. Specifically, we estimate the following:

¹² We also estimate each of the supply factor in separate regressions. The results are quantitatively similar.

¹³ Collateral value is only available for housing loan.

¹⁴ Market share refers to the share of loan applications in each bank during the year.

$$Prob(Loan Approval)_{i,j,t} = \beta_{ILAM,t} + \beta_0 D_{i,t} + \boldsymbol{\beta}_1 \mathbf{S}_{j,t=1} + \boldsymbol{\beta}_2 \mathbf{X}_{i,j,t} + \beta_3 Z_t + \varepsilon_{i,j,t} \quad (2)$$

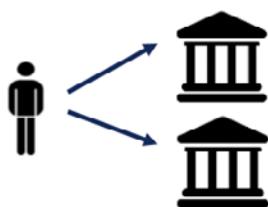

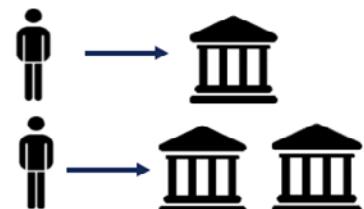

where similar to Equation 1, i refers to individual i who applied to bank j at time t . We estimate Equation 2 using the linear probability model as well.

$\beta_{ILAM,t}$ refers to the *industry-location-age-marital-time* fixed effect. This is the key difference from Equation 1. Intuitively, borrowers will be placed into bins based on their occupation, location of residence, age and marital status. These are the available characteristics in the dataset that can determine loan demand. The underlying assumption is individuals in the same bin will have a similar level of credit demand based on these characteristics.

The coefficient of interest under this method is β_0 . This captures the impact of the demand factor $D_{i,t}$ on the probability of loan approval. We proxied $D_{i,t}$ with borrower i 's income from the income tax database.

Similar to Equation 1, the dependent variable is a dummy variable representing the status of loan applications. $\mathbf{S}_{j,t=1}$ is the vector of supply factors for bank j at time 1, $\mathbf{X}_{i,j,t}$ refers to the vector of controls and Z_t refers to the time fixed effect.

The coefficient of interest under this method is β_0 and β_1 . With these two coefficients, we can compare the relative strength of demand and supply factors. If $\beta_0 > \beta_1$, demand factor is stronger than the supply factors in household loan approval. Standard errors are clustered at industry-location-age-marital-time level.

First strategy (Equation 1)Only individuals who applied to multiple banks**Second strategy (Equation 2)**All individuals

- Using individual-year fixed effect
- Since the comparison is across banks for the *same* individual, only differences in banks' characteristics will affect the probability of loan approval
- Coefficient of interest is β_1 in Equation 1. This is the effect from the supply factors

- Using industry-location-age-marital-year fixed effect
- We can compare the relative strength of demand (proxied by individual's income) and supply factors for the same *group* of individuals
- Coefficient of interest is β_0 (demand factor) vs β_1 (supply factors) in Equation 2

Source: Author's illustration.

5. Results

5.1 Results from Method 1

Table 2 in Appendix shows the results using Equation 1. Column 1 shows the result for housing loan and column 2 for car loan.

The results show that banks' balance sheet matters. Banks with a higher funding ratio and capital ratio is more likely to approve a housing and car loan. A one standard deviation increase in the banks' funding ratio and capital ratio would increase the probability of approval for a housing loan by 0.06 and 0.04 respectively, which represents a 9% and 5% increase in the probability of approval from the mean¹⁵ probability of approval. Similar results are observed for a car loan. However, the impact of liquidity ratio is different between a housing and car loan. It does not have a significant impact on the probability of housing loan approval but it does affect the car loan approval negatively. Banks with a higher liquidity ratio are more likely to reject the car loan application. A one standard deviation increase in banks' liquidity ratio leads to a decline in the probability of a car loan approval by 0.04, which is a 6% decrease from the mean.

Among the supply factors, the funding ratio of the banks is the strongest determinant of household lending. As illustrated in Table 2 the size of the coefficient for the funding ratio is at least twice the size for the capital ratio and liquidity ratio.

5.2 Results from Method 2

Table 3 in Appendix displays the results for Method 2. We replace individual-time fixed effect with industry-location-age-marital-time fixed effect. The advantage of this method is discussed at the earlier section.

Similar to the results from Equation 1, banks with a higher funding ratio and capital ratio are more likely to approve a housing loan and car loan. A one standard deviation increase in the banks' funding ratio and capital ratio increase the probability of housing loan approval by 0.05 and 0.03 respectively, which represents a 7% and 4% increase from the mean probability of approval. Similar results are observed for car loan approvals. In addition, banks with a higher liquidity ratio are less likely to approve a housing loan and car loan, especially the latter.

Under this method, we can compare the relative strength of demand and supply factors. From Table 3, we observe that a one standard deviation increase in the monthly income of the borrowers increases the probability of approval by 0.03, which represents a 5% increase in the probability of approval from the mean. This magnitude is smaller than the impact from funding ratio and comparable to that of capital ratio. This supports the case where $\beta_0 < \beta_1$ in which the supply factor is stronger than the demand factor in determining the housing and car loan approvals.

It is worth highlighting the potential selection issue in this sample that may explain the strength of the income factor. Given that borrowers in our sample paid income tax and applied for loans, they are likely to have a higher income level than

¹⁵ The mean probability of approval for a housing loan is 0.7, and for a car loan is 0.8. This is estimated from the constant term in the regression as shown in Table 2.

the general population. This may create a downward bias to the income result. The role of income may be much stronger if we take into account the broader population, especially those who did not file the income tax return forms or those who did not have access to submit a loan application.

6. Discussion and Policy Implications

The micro-level results show that banks' funding ratio is the strongest determinant of household lending in Malaysia during the 2014-2016 period. This is consistent with the fact that deposit constitutes the main supply of loanable funds for banks in Malaysia and thus may act as the driving force of bank lending (see Chart 4). Banks with a lower funding ratio may thus be more risk-averse and restrictive in their lending activities.

The positive relationship between the capital ratio and lending activities is supported by the role of bank capital that acts as a buffer to insulate banks from the risk of insolvency (Rajan (1994); Jokipii and Milne (2008)). Banks with a higher level of capital can therefore accommodate a faster loan growth than banks with lower capital due to their higher capacity to absorb more losses in the event of a loan default (Kosak et al. (2014)).

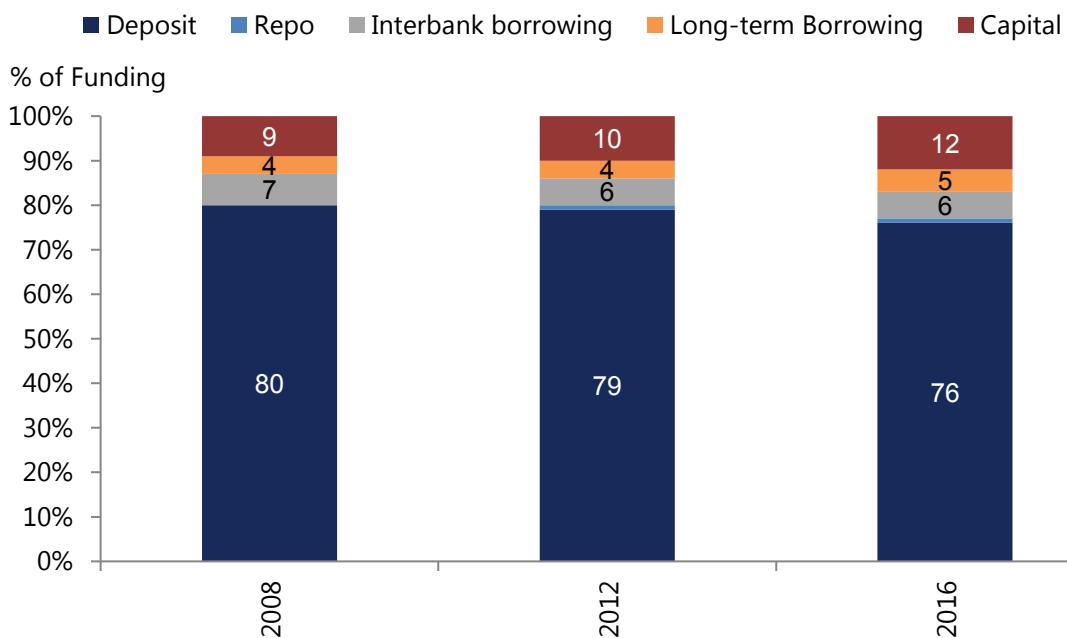

However, the negative relationship between the liquidity ratio and lending activities is an interesting finding. A higher liquidity ratio should enable banks to draw down their cash and securities to meet any unexpected cash outflows without adjusting their loan portfolio (Gambacorta (2005); Kashyap and Stein (2000)). However, for the case of Malaysia, banks that have more liquid assets extend fewer car loans. More investigation is required to understand this unique feature of Malaysian banks.

Our findings on the importance of the funding ratio may explain the moderation in aggregate household loan approval growth during the 2014-2016 period. Household loan approval growth in Malaysia, especially for housing and car loans, has been declining despite stable GDP growth (Chart 5). Our micro-level findings suggest that the moderation may be driven more by the supply factors instead of demand. As shown in Chart 6, the aggregate funding ratio in the banking system did decline quite substantially during this period due to high net external outflow¹⁶.

GDP Growth and Household Loan Approval Growth

Chart 5

Source: Author's estimate.

Source: Author's estimate.

Our study could therefore serve as a starting point to discuss the impact of policies on banks' balance sheet and ultimately lending activities. In particular, our empirical findings on the importance of banks' funding ratio in credit extension have several policy implications. First, the results highlight the importance of promoting developments in the financial system to encourage diversification in the sources of funding for financial institutions. For example, a deeper bond and equity market will reduce banks' heavy reliance on deposit as the primary source of funding, which will help decrease the sensitivity of lending activities to movements in deposit.

Second, the unequal distribution of deposit in the banking system may have a non-trivial impact on the lending activities of smaller banks. Unlike the large banks, small banks rely more on deposit as their primary source of funding. Due to the lower concentration of deposit among the small banks, this may potentially affect their willingness to lend given the lack of available funds.

However, there are several key limitations to our findings. First, as highlighted in the previous section, there are selection issues in our sample. Only individuals who filed the income tax and applied for loans are captured in our dataset. Also, many banks in Malaysia pre-filter the loan applications by income. Thus any prospective applicants who are below a certain income threshold may have already been rejected before they are registered in the credit register.

Second, unlike the supply indicators, we have limited demand indicators in the dataset. Only income and basic households' characteristics such as age, marital status, the location of residence and industry are available in the dataset. Other important factors such as the historical credit score and the debt-service ratio (DSR) of the applicants are not available. Of note, we also do not observe the price of the loan (i.e., the interest rate) offered to the applicants, which limit our analysis to only the quantity of loans.

Third, it is also important to note that the role of demand and supply factors may change depending on the economic environment. For example, using a dataset of loan applications covering Spain from 2002 to 2010, Jimenez et al. (2012) found that banks' balance-sheet only matters during crisis periods. Firms' balance-sheet, on the other hand, matters in both good and bad periods. Unfortunately, for Malaysia, the time period of 2014-2016 is too short to differentiate the channels during good and bad economic periods, which we leave for future research.

7. Conclusion

This paper aims to trace how supply and demand factors affect household loan approval. We create a borrower-bank pair dataset to do the isolation. We utilise two different methods to disentangle the demand and supply factors. There are two key findings from our results. First, we find that banks' balance sheet (the supply factors) matters. Second, we find that the supply factors affect household loan approval more than the demand factor. The declining funding ratio due to high net external outflows can potentially explain the moderation in the aggregate household loan approval growth between 2014 and 2016. Overall, the findings in our paper fill a research gap for the Malaysian economy by identifying the role of banks' balance sheet in household lending. Our empirical findings on the importance of the funding ratio could serve to inform the calibration of policies especially those in relation to lending activities.

8. Appendix

Table 1: Summary Statistics

Variables	Mean	S.D.
Banks' Characteristics		
Funding ratio (%)	75	13.5
Capital ratio (%)	13.7	5.6
Liquidity ratio (%)	11.6	9.7
Size (Log total assets)	10.5	1.2
Borrowers' Characteristics		
Monthly income (RM)	9016.1	15030.1
Loan Application amount (RM, thousand)	246.9	340.6
Collateral value for housing loan only (RM, thousand)	2438	10500

Observations	247,069	354,598

Robust standard errors in brackets, *** p<0.01, ** p<0.05, * p<0.1

*Note: Table 2 shows the results from Equation 1. The regression examines how the probability of loan approval is affected by the supply factors. This is estimated using the sample of borrowers who applied to multiple banks. Housing loan and car loan applications are estimated separately in Column 1 and Column 2. We use a linear probability model for estimation. The dependent variable is a dummy variable to indicate the status of loan applications (1 if approved, 0 if rejected). Individuals' characteristics are absorbed by the individual-time fixed effect. The key independent variables are banks' supply factors (capital ratio, funding ratio and liquidity ratio) at the beginning of the year. Controls include the loan application amount, the collateral value, the size and the market share of banks. All variables are standardised for ease of comparison. Only new loan applications are considered. Robust standard errors in parentheses.

Table 3: Effect of demand and supply factors on the status of loan applications (using all individuals (Equation 2))

Dependent variable	Status of Loan Applications (1 if accepted, 0 otherwise)	
	[Column 1: Housing Loan]	[Column 2: Car Loan]
Standardised Monthly Income	0.029*** [0.004]	0.025*** [0.003]
Standardised Capital Ratio	0.025*** [0.001]	0.056*** [0.001]
Standardised Funding Ratio	0.051*** [0.001]	0.064*** [0.001]
Standardised Liquidity Ratio	-0.014*** [0.001]	-0.045*** [0.001]
Constant	0.683*** [0.005]	0.847*** [0.004]
Loan's Characteristics Controls		
Loan Application Amount (Value)	Yes	Yes
Collateral Value	Yes	No
Bank's Characteristics Controls		
Size of Bank	Yes	Yes
Bank's Market Share	Yes	Yes
Time fixed effect	Yes	Yes
Loan Type	Housing	Car
Observations	263,058	399,573

Robust standard errors in brackets, *** p<0.01, ** p<0.05, * p<0.1

*Note: Table 3 shows the results from Equation 2. The regression examines how the probability of loan approval is affected by both demand and supply factors. This is estimated using the sample of all borrowers. Housing loan and car loan applications are estimated separately in Column 1 and Column 2. We use a linear probability model for estimation. The dependent variable is a dummy variable to indicate the status of loan applications (1 if approved, 0 if rejected). Individuals' characteristics are absorbed by the industry-location-age-marital-time fixed effect. The key independent variables include banks' supply factors (capital ratio, funding ratio and liquidity ratio) at the beginning of the year and the demand factor proxied by individuals' monthly gross income. Controls include the loan application amount, the collateral value, the size and the market share of banks. All variables are standardised for ease of comparison. Only new loan applications are considered. Robust standard errors in parentheses.
