Frequency of Observation and the Estimation of Integrated Volatility in Deep and Liquid Financial Markets*

September 2007

Abstract

Using two newly available ultrahigh-frequency datasets, we investigate empirically how frequently one can sample certain foreign exchange and U.S. Treasury security returns without contaminating estimates of their integrated volatility with market microstructure noise. Using volatility signature plots and a recently-proposed formal decision rule to select the sampling frequency, we find that one can sample FX returns as frequently as once every 15 to 20 seconds without contaminating volatility estimates; bond returns may be sampled as frequently as once every 2 to 3 minutes on days without U.S. macroeconomic announcements, and as frequently as once every 40 seconds on announcement days. With a simple realized kernel estimator, the sampling frequencies can be increased to once every 2 to 5 seconds for FX returns and to about once every 30 to 40 seconds for bond returns. These sampling frequencies, especially in the case of FX returns, are much higher than those often recommended in the empirical literature on realized volatility in equity markets. We suggest that the generally superior depth and liquidity of trading in FX and government bond markets contributes importantly to this difference.

Any remaining errors are obviously our own.
# 1 Introduction

Modeling, measuring, and estimating the volatility of financial asset returns is important for many economic and financial applications, including forecasting and analyzing alternative decisions available to investors and policy makers. One approach to estimating volatility is to use a parametric framework, such as the class of ARCH, GARCH, and stochastic volatility models. If data on returns are available at sufficiently high frequencies, one can also estimate volatility nonparametrically by computing the \textit{realized} volatility, which is the natural estimator of the ex post \textit{integrated} volatility. This latter method is appealing both because it is computationally simple and because it is a valid estimator under fairly mild statistical assumptions. In principle, the higher the sampling frequency is, the more precise the estimates of integrated volatility become. In practice, however, the presence of so-called market microstructure features at very high sampling frequencies may create important complications. The finance literature has identified many such features; among them are the fact that financial transactions—and hence price changes and non-zero returns—arrive discretely rather than continuously over time, the fact that buyers and sellers usually face different prices (separated by the bid-ask spread), the presence of negative serial correlation of returns to successive transactions (including the so-called bid-ask bounce), and the price impact of trades. For an overview of many of these market microstructure issues and their importance for financial theory and practice, we refer the reader to, e.g., the books by Hasbrouck (2006), O’Hara (1998), and Campbell et al. (1997, Ch. 3), as well as the journal articles by Roll (1984), Harris (1990, 1991), and Hasbrouck (1991).

The presence of market microstructure features is generally believed to elevate estimates of integrated volatility, especially at the very highest sampling frequencies, relative to the base case of no market microstructure noise. However, this need not always be the case. For example, if an organized stock exchange has designated market makers and specialists, and if these participants are slow in adjusting prices in response to shocks (possibly because the exchange’s rules explicitly prohibit them from adjusting prices by larger amounts all at once), it may be the case that realized volatility could drop if it is computed at those sampling frequencies for which this behavior is thought to be relevant.\footnote{In fact, Hansen and Lunde (2006) record as one of their empirical “facts” that market microstructure noise is negatively correlated with the returns, and hence biases the estimated volatility downward. However, as we show in this paper, this empirical stylized fact—which is based on their analysis of high-frequency stock returns—does not seem to carry over to the foreign exchange and bond markets.} In any case, it is widely recognized that market microstructure issues can \textit{contaminate} estimates of integrated volatility in important ways, especially if the data are sampled at ultra-high frequencies, as is becoming more and more common.

Two different approaches have emerged to dealing with the issue of contamination by market microstructure when estimating integrated volatility. The first approach, which is reportedly the more common one, is simply to sample sufficiently sparsely so that any market microstructure issues should not be a significant
concern. This approach is appealing because it permits the use of the intuitive and simple standard realized volatility estimator, and also because it does not require making any assumptions about the nature of the market microstructure noise. However, the choice of sampling frequency is typically somewhat ad hoc, and it could lead to inefficient estimates of integrated volatility if the sampling frequency is chosen too conservatively, i.e., too low. In an attempt to address this concern, Aït-Sahalia et al. (2005) and Bandi and Russell (2006b) have proposed optimal sampling frequency rules that are based on a bias-variance trade-off, viz., between sampling more often and incurring a larger bias and sampling less often and incurring larger variance. Interestingly, whereas much of the early empirical work on estimating integrated volatility was performed using FX market data (e.g., Zhou, 1996, and Andersen, Bollerslev, Diebold, and Labys, 2001), much of the more recent work in this field, especially on the optimal choice of sampling frequency, has been applied to markets for individual stocks (e.g., Bandi and Russell, 2006b, and Hansen and Lunde, 2006).

The second approach is to design alternative estimators of integrated volatility that are less sensitive than the basic realized volatility estimator to the presence of market microstructure noise. This approach, which generally relies on kernel-based or subsampling methods to let researchers use returns sampled at higher frequencies, potentially should allow for a more efficient use of the data. A drawback is that the computation of these estimators may be considerably more complicated than that of the standard realized volatility estimator. Moreover, these more robust estimators may give up some of the standard estimator’s appealing simplicity and intuitiveness. These concerns, however, may be overblown in practice. For instance, in this paper we find that a very simple version of a kernel-based estimator can substantially improve upon the performance of the standard estimator, in the sense of permitting the use of much-higher sampling frequencies to estimate integrated volatility without incurring market microstructure-induced bias.

The first aim in the empirical section of our paper is to study, for two specific financial assets, how the standard estimator of integrated volatility is affected by the choice of sampling frequency. The two assets we study are traded in some of the deepest and most liquid financial markets in existence today; they are the spot exchange rate of the dollar/euro currency pair, obtained from Electronic Broking Systems (EBS), and the price of the on-the-run 10-year U.S. Treasury note, traded on BrokerTec. Both of these markets are electronic order book systems, which quite likely represent the future of wholesale financial trading systems. Both markets are strictly inter-dealer. These markets are far larger in terms of total trading volume than markets for individual stocks—even the most liquid handful of stocks traded on the New York Stock Exchange—, and bid-ask spreads are narrower than in typical stock markets. In 2005, bid-ask spreads averaged 1.04 basis points for dollar/euro spot transactions on EBS and 1.68 basis points for 10-year Treasury note transactions on BrokerTec. The two time series are available at ultra-high frequencies—up to the second-by-second frequency.
Our main hypothesis is that, in such deep and liquid markets, market microstructure noise should pose less of a concern for volatility estimation, in the sense that it should be possible to sample returns on such assets more frequently than say, returns on individual stocks, before estimates of integrated volatility encounter significant bias caused by the markets’ microstructure features. This thesis is indeed borne out by our empirical work. We show that it is possible to sample the FX data as often as once every 15 to 20 seconds without the standard estimator of integrated volatility showing discernible effects stemming from market microstructure noise. The corresponding sampling interval lengths for returns on 10-year Treasury notes are between 2 and 3 minutes. These intervals are shorter than the sampling intervals of several minutes, usually five or more minutes, that have often been recommended in the empirical literature on estimating integrated volatility for a number of financial markets. These shorter sampling intervals and associated larger sample sizes afford a considerable gain in estimation precision. We conclude that in very deep and liquid markets, microstructure-induced frictions may be much less of an issue for volatility estimation than was previously thought. We also confirm the results of several previous empirical studies that major macroeconomic announcements systematically affect integrated volatility. In addition, we show that the optimal choice of sampling frequency is higher—and the sampling interval lengths are therefore lower—on days with scheduled U.S. macroeconomic announcements.

Although the sampling frequencies at which the standard realized volatility estimator can be used are already very high for the two empirical time series we consider in this paper, it is possible to sample at even higher frequencies by using so-called kernel estimators, which are designed explicitly to control for the effects of market microstructure noise. These estimators can be viewed as the equivalent of so-called robust variance estimators in the traditional time series econometrics literature. We find that by using a very simple version of a kernel estimator, it is possible to sample FX returns at frequencies as high as once every 2 to 5 seconds, and that bond returns can be sampled as frequently as once every 30 to 40 seconds. This estimator, which is almost as easy to compute as the standard realized volatility estimator, thus offers a substantial additional gain in efficiency in terms of how often one can sample on an intraday basis.

Finally, we also examine how certain alternative estimators and measures of daily variation perform for the two time series at hand. These alternative estimators are not based on functions of the standard quadratic variation process, but instead on functions of absolute variation and bipower variation processes. A reason for considering such methods is that they may be more robust than the standard estimator to outlier activity (heavy tails) in the data and, in particular, to jumps that may occur in the price series. In general, these estimators measure somewhat different (but highly relevant) aspects of daily variation than does the standard realized volatility estimator. We find some evidence that these alternative methods are indeed more robust than the standard estimator to the presence of jumps in the returns series. Specifically, estimates
of integrated volatility that are based on absolute variation show less dispersion across announcement and non-announcement days than estimates that are based on squared variation. However, we find no evidence that these robust methods are also less sensitive than the standard estimator with regard to bias imparted by market microstructure noise. To the contrary, our results indicate that one should typically sample less frequently when using these robust estimators, relative to the optimal sampling frequency found for the standard volatility estimator.

The remainder of our paper is organized as follows. Section 2 provides some motivation for the use of the standard estimator of integrated volatility, which is based on the quadratic variation of returns. The section also details how market microstructure noise may cause bias in the standard estimator, provides an introduction to kernel-based estimators designed to circumvent this problem, and sets out the use of absolute and bipower variation processes. Section 3 provides an overview of the characteristics of the foreign exchange and bond market data used in our empirical work. Section 4 provides the empirical results for the standard estimator of realized volatility, using volatility signature plots and the Aït-Sahalia et al. (2005) and Bandi and Russell (2006b) rule for choosing sampling frequencies. Section 5 shows the results from the realized kernel estimators. Section 6 provides the estimation results for the robust estimators of realized volatility, such as the one that is based on the absolute variation process. Section 7 provides a discussion of some broader issues raised by our empirical findings, and Section 8 concludes.

2 Motivation and estimation techniques

2.1 Motivation

The fundamental idea behind the use of realized volatility and high-frequency data is that quadratic variation can be used as a measure of ex-post variance in a diffusion process. The quadratic variation $QV_t$ of a process $X_t$ is defined as

$$QV_t = [X, X]_t = p \lim_{n \to \infty} \sum_{j=1}^{n} (X_{t_j} - X_{t_{j-1}})^2,$$

for any sequence of partitions $0 = t_0 < t_1 < \cdots < t_n = t$ with sup $j |t_j - t_{j-1}| \downarrow 0$ as $n \to \infty$ (see, for instance, Andersen, Bollerslev, Diebold, and Labys, 2003, and Barndorff-Nielsen and Shephard, 2004a). If $X_t$ follows a standard diffusion process, such as

$$X_t = \int_0^t a_u \, du + \int_0^t \sigma_u \, dW_u,$$
where \( W_u \) is standard Brownian motion, and if \( a_u \) and \( \sigma_u \) satisfy certain regularity conditions, then

\[
[X, X]_t = \int_0^t \sigma_u^2 \, du.
\] (3)

In this model, which is frequently used in financial economics, the quadratic variation measures the integrated variance over some time interval and is thus a natural way of measuring the ex-post variance. For most of the discussion, and unless otherwise noted, we will maintain the assumption that the logarithm of the price process follows the diffusion process in equation (2). This is not crucial to the analysis in the paper, but it facilitates the exposition of the theoretical concepts outlined below. In Section 2.5 below, we discuss the effects of adding a jump component to equation (2).

Suppose the log-price process \( X_t \) is sampled at fixed intervals \( \delta \) over some time period \([0, t]\). Let \( n = \lfloor t/\delta \rfloor \).

The realized variance, given by

\[
RV_t = \sum_{j=1}^n (X_{j\delta} - X_{(j-1)\delta})^2, \tag{4}
\]

is a natural estimator of the quadratic variation over the interval \([0, t]\). In practice, we usually consider the integrated volatility, which is the square root of the integrated variance, and the corresponding realized volatility, which is obtained by taking the square root of \( RV_t \).

The properties of \( RV_t \) have been analyzed extensively in the econometrics literature.\(^2\) In particular, it has been shown that under very weak conditions realized variance is a consistent estimator of quadratic variation. That is, for a fixed time interval \([0, t]\), \( RV_t \rightarrow_p QV_t \) as \( \delta \downarrow 0 \). In addition, if \( X_t \) satisfies equation (2), the limiting distribution of \( RV_t \) is mixed normal and is centered on \( QV_t \):

\[
\sqrt{n}(RV_t - QV_t) \Rightarrow MN(0, 2Q_t), \tag{5}
\]

where \( Q_t = \int_0^t \sigma_u^4 \, du \) is called the quarticity of \( X_t \).

### 2.2 Market microstructure noise

According to the asymptotic result in equation (5), it is preferable to sample \( X_t \) as frequently as possible in order to achieve more precise estimates of the quadratic variation. However, in practice, price changes in financial assets sampled at very high frequencies are subject to market frictions—such as the bid-ask bounce and the price impact of trades—in addition to reacting to more fundamental changes in the value of the

\(^2\)The asymptotic properties of realized volatility and other related estimators have been primarily developed in a series of papers by Barndorff-Nielsen and Shephard (e.g., 2001, 2002ab, 2003, 2004ab, 2006). Other important contributions include, for instance, Andersen, Bollerslev, Diebold, and Labys (2001, 2003). A survey of this literature is given in Barndorff-Nielsen and Shephard (2005).
asset. Suppose the observed price $X_t$ can be decomposed as

$$X_t = Y_t + U_t,$$  \hspace{1cm} (6)

where $Y_t$ is the so-called latent price process and $U_t$ represents market microstructure noise. The object of interest is now the quadratic variation of the unobserved process $Y_t$, which is assumed to satisfy the diffusion given by equation (2). A standard assumption is that $U_t$ is a white noise process, independent of $Y_t$, with mean zero and constant variance $\omega^2$. Now, as $\delta$, the length of sampling intervals, goes to zero, the squared increments in $X_t$ will be dominated by the changes in $U_t$. This follows because the increments in $Y_t$ are of order $O_p(\sqrt{\delta})$ under equation (2), whereas the increments in $U_t$ are of order $O_p(1)$ regardless of sampling frequency. Calculating the realized variance using extremely high frequency (such as second-by-second) returns from the observed price process $X_t$ will therefore result in a biased and inconsistent estimate of the quadratic variation of the latent price process $Y_t$.

2.3 Optimal choice of sampling frequency

The initial reaction to this problem was simply to sample at frequencies for which market frictions are believed not to play a significant role. Even with this limitation, daily volatility estimates can be obtained with some precision. In particular, sampling prices and returns at the five-minute frequency appears to have emerged as a popular choice to compute daily-frequency estimates of volatility. In order to formalize this line of reasoning, Bandi and Russell (2006b) derive an optimal sampling frequency rule for the standard realized variance estimator.\(^3\) Their rule is based on a function of the signal-to-noise ratio between the innovations to the latent price process and the noise process. Their key assumption is that by sampling at the highest possible frequency, it may be possible to obtain a consistent estimate the variance of the noise, $\omega^2$. For example, let $\delta^{1\text{sec}}$ denote the one-second sampling frequency, which is the highest possible in our data, and let $n^{1\text{sec}}$ denote the number of non-zero one-second returns during the day; i.e., $n^{1\text{sec}}$ counts the number of one-second periods during the whole day for which there is actual market activity that moves the price. An estimator of $\omega^2$ is now given by

$$\hat{\omega}^2 = \frac{1}{2n^{1\text{sec}}} \sum_{j=1}^{n^{1\text{sec}}} (X_{j\delta^{1\text{sec}}} - X_{(j-1)\delta^{1\text{sec}}})^2,$$  \hspace{1cm} (7)

\(^3\)Aït-Sahalia et al. (2005) study optimal sampling frequency rules that are similar to that given by Bandi and Russell (2006b). Based on the market microstructure model of Roll (1984), they suggest that the variance of the market microstructure noise can be calculated from the bid-ask spread in the data. In particular, if $s$ is the bid-ask spread in the market (expressed in percent of the price), then $\omega^2 = s^2/4$. However, as Aït-Sahalia et al. (2005) point out, by estimating $\omega^2$ strictly from the bid-ask spread, the contributions of any other sources to microstructure noise are ignored. The resulting estimate of $\omega^2$ should therefore be interpreted as a lower bound on the actual variance of the noise.
where the summation is carried out over the $n^{1\text{ sec}}$ intervals with nonzero returns. By estimating $\omega^2$, the strength of the noise in the returns data can thus be measured. The strength of the signal, i.e., variations in $X_t$ which come from the latent price process $Y_t$, can be measured by the quarticity of that process. By relying on data sampled at a lower frequency, such as once every ten minutes, where the market microstructure noise should not be an issue, the quarticity of $Y_t$ can be estimated consistently (though not efficiently) by

$$\hat{Q}^{10\text{ min}} = \frac{n^{10\text{ min}}}{3} \sum_{j=1}^{n^{10\text{ min}}} (X_{j\delta^{10\text{ min}}} - X_{(j-1)\delta^{10\text{ min}}})^4,$$

where $n^{10\text{ min}}$ is the number of 10-minute intervals with non-zero returns in a day. Thus, by using returns obtained by sampling at different frequencies, it is possible to assess the relative importance of the signal $Y_t$ and the noise $U_t$. Bandi and Russell (2006b) show that an approximate rule of thumb for the optimal sampling frequency, $\delta^{\text{opt}} = 1/n^{\text{opt}}$, is given by

$$n^{\text{opt}} = \left(\frac{\hat{Q}^{10\text{ min}}}{(2\hat{\omega}^2_{1\text{ sec}})^2}\right)^{1/3}. \tag{9}$$

### 2.4 Estimators of integrated volatility that are robust to the presence of high-frequency market microstructure noise

The other approach to dealing with the microstructure noise issue is to design estimators that explicitly control for and potentially even eliminate its effects on volatility estimates. At the cost of some loss of simplicity, this approach has the potential of extracting useful information that would otherwise be discarded if a coarser sampling scheme is employed. A number of estimators have been proposed recently to deal with market microstructure noise in this manner; see, for instance, Aït-Sahalia et al. (2005, 2006), Hansen and Lunde (2006), Oomen (2005, 2006), Zhang (2006), and Zhang et al. (2005). While these recently-proposed estimators possess several desirable properties, such as asymptotic consistency under their respective maintained assumptions and (in some cases) asymptotic efficiency as well, the actual performance of these estimators in empirical practice remains a topic of ongoing research.

Here, we focus on an estimator proposed by Barndorff-Nielsen, Hansen, Lunde, and Shephard (2006), hereafter BNHLS. Define the realized autocovariation process

$$\gamma_h (X_\delta) = (1-h\delta)^{-1} \sum_{j=h+1}^{n} (X_{j\delta} - X_{(j-1)\delta}) (X_{(j-h)\delta} - X_{(j-h-1)\delta}), \tag{10}$$

\text{Related studies include Andersen, Bollerslev, Diebold, and Ebens (2001) and Zhou (1996). Bandi and Russell (2006a) and Barndorff-Nielsen and Shephard (2005) provide surveys.}
for $h \geq 0$, where the term $(1 - h\delta)^{-1}$ is a small-sample correction factor. The realized kernel estimator in BNHLS is given by

$$
\tilde{K}_t(X_\delta) = \gamma_0(X_\delta) + \sum_{h=1}^{H} k\left(\frac{h-1}{H}\right) \left( \gamma_h(X_\delta) + \gamma_{-h}(X_\delta) \right),
$$

(11)

for some kernel function $k(\cdot)$ satisfying $k(0) = 1$ and $k(1) = 0$ and for a suitably chosen lag truncation or bandwidth parameter $H$. The first term in equation (11), $\gamma_0(X_\delta)$, is identical to the standard realized variance estimator; the second term, the weighted sum of autocovariances up to order $H$, can thus be viewed as a correction term which aims to eliminate the serial dependence in returns induced by microstructure noise.

The estimator given in equation (11) is obviously a natural analogue of the well-known heteroskedasticity and autocorrelation consistent (HAC) estimators of long-run variances in more typical econometric settings.

Apart from realized kernel estimators, so-called subsampling estimators (e.g., Zhang et al., 2005) have also been proposed to correct for the effects of market microstructure noise. Subsampling estimators are, in fact, very closely related to realized kernel estimators; see Aït-Sahalia et al. (2006), BNHLS, as well as the discussion of the quadratic form representation in Andersen et al. (2006). To keep the empirical exposition below more manageable, we chose to focus only on the kernel approach in this paper. We leave to future research an explicit comparison of the relative performance of kernel estimators and subsampling estimators for the two time series we consider in this paper.

### 2.5 Absolute power and bipower variation methods

Any estimator that is based on squared values of observations will, to some extent, be sensitive to the occurrence of outliers in the data in general, and, within the framework of financial models, to jumps in asset prices in particular. In the tradition of robust econometric estimation, absolute-value versions of the realized variance estimator have therefore been considered. Barndorff-Nielsen and Shephard (2004b) consider the following normalized versions of realized absolute variation and realized bipower variation. They set

$$
RAV_t = \mu_1^{-1} n^{-1/2} \sum_{j=1}^{n} |X_{j\delta} - X_{(j-1)\delta}|
$$

(12)

and

$$
RBV_t = \mu_1^{-2} (1 - \delta)^{-1} \sum_{j=2}^{n} |X_{j\delta} - X_{(j-1)\delta}| |X_{(j-1)\delta} - X_{(j-2)\delta}|
$$

(13)

In our empirical work, we rely exclusively on the Modified Tukey-Hanning kernel defined in BNHLS, which additionally satisfies $k'(0) = k'(1) = 0$ and is asymptotically the most efficient of the kernels considered by them. The Modified Tukey-Hanning kernel function is given by $k(x) = (1 - \cos(x(1-x)))/2$, $x \in [0, 1]$. The bandwidth parameter $H$ is set equal to $\hat{c} n^{1/2}$, where $\hat{c}$ is a constant given in BNHLS. In the case when all (or almost all) available data are used, i.e., when the data sampled at or close to the highest available frequency, BNHLS recommend using $H = \hat{c} n^{2/3}$; we will rely on this bandwidth choice for sampling intervals shorter than 30 seconds.
where \( \mu_1 = E[Z] = \sqrt{2/\pi} \approx 0.798 \) and \( Z \) is a standard normal random variable. In contrast to the definitions of the realized variance and realized bipower estimators, it is necessary to use a scaling factor, \( n^{-1/2} \), in equation (12) so that \( RAV_t \) converges to a proper limit as \( n \to \infty \). The term \((1 - \delta)^{-1}\) in equation (13) is a small-sample correction factor.

In the absence of market microstructure noise and assuming that equation (2) holds, Barndorff-Nielsen and Shephard (2004b) show that \( RAV_t \) and \( RBV_t \), respectively, are consistent estimators of the quantities \( \int_0^t \sigma_u^2 \, du \) and \( \int_0^t \sigma_u^2 \, du \). Hence, realized bipower variation provides an alternative estimator of the integrated variance of \( X_t \). The usefulness of realized bipower variation stems from the fact that it has been shown to provide a consistent estimator of \( \int_0^t \sigma_u^2 \, du \) under much more general conditions than realized squared variation does. In particular, suppose that \( X_t \) exhibits jump shocks as well as diffusive innovations, such that

\[
X_t = \int_0^t a_u \, du + \int_0^t \sigma_u \, dW_u + \sum_{j=1}^{N_t} c_j, \tag{14}
\]

The process \( N_t \) is a jump counting process, which is assumed to be finite for all \( t \), and the coefficients \( c_j \) are the sizes of the associated jumps.\(^6\) The quadratic variation of \( X_t \) is now given by

\[
[X, X]_t = \int_0^t \sigma_u^2 \, du + \sum_{j=1}^{N_t} c_j^2, \tag{15}
\]

and the realized variation converges to this term as \( \delta \downarrow 0 \). However, the realized absolute variation and the realized bipower variation are still consistent estimators of \( \int_0^t \sigma_u^2 \, du \) and \( \int_0^t \sigma_u^2 \, du \), respectively. By calculating both the realized variation and the realized bipower variation of \( X_t \), one can separate the total quadratic variation into its continuous and jump components. This is useful, for instance, in volatility forecasting, because the jump component of the total quadratic variation is, in general, far less persistent than the diffusive component (Andersen et al., 2005).

Even though the limit of the realized absolute variation, \( \int_0^t \sigma_u \, du \), has no direct use in most financial applications, such as the pricing of options, Forsberg and Ghysels (2006) and Ghysels et al. (2006) report that it is, empirically, a very useful predictor of future quadratic variation. Since predicting future volatility is often the ultimate goal, we therefore also discuss in our paper how often to sample when estimating the absolute variation of the returns to a financial time series that is obtained from deep and liquid markets; in particular, we examine how estimates of realized absolute variation may be affected by market microstructure noise in such markets. So far, there has been little work aimed at dealing with the presence of market microstructure

\(^6\)Equation (2) is thus a special case of (14), with \( N_t \equiv 0 \) or, equivalently, \( c_j \equiv 0 \) for all \( j \). The assumption that \( N_t \) is finite for all \( t \) rules out certain processes, such as stable-Lévy processes. Stable-Lévy processes are characterized by an infinite number of jumps in any time interval. See Calvet and Fisher (2002) for an overview of the theory and empirical evidence of multifractal asset returns in finance; multifractal processes are also characterized by an uncountable number of jumps.
noise when calculating realized absolute and bipower variation. The only attempt that we are aware of is a paper by Andersen et al. (2005). They suggest using staggered, or skip-one, returns to mitigate spurious autocorrelations in the returns that may occur due to microstructure-induced noise. That is, they suggest using the following modified version of equation (13),

$$RBV_{1,t} = \mu_1^{-2}(1 - 2\delta)^{-1} \sum_{j=3}^{n} \left[ X_{j\delta} - X_{(j-1)\delta} \right] \left[ X_{(j-2)\delta} - X_{(j-3)\delta} \right].$$

(16)

3 The data

3.1 The foreign exchange data

We analyze high-frequency spot dollar/euro exchange rate data from EBS (Electronic Broking System) spanning January through December 2005. EBS operates an electronic limit order book system used by virtually all foreign exchange dealers across the globe to trade in several major currency pairs. Since the late 1990s, inter-dealer trading in the spot dollar/euro exchange rate, the most-traded currency pair, has, on a global basis, become heavily concentrated on EBS. As a result, over our sample period EBS processed a clear majority of the world’s inter-dealer transactions in spot dollar/euro. Publicly available estimates of EBS’s share of global trading volume in 2005 range from 60% to 90%, and prices on the EBS system were the reference prices used by all dealers to generate FX derivatives prices and spot prices for their customers. Further details on the EBS trading system and the data can be found in Chaboud et al. (2004) and Berger et al. (2005).

The exchange rate data we use are the midpoints of the highest bid and lowest ask quotes in the EBS limit-order book at the top of each second. The exchange rate is expressed as dollars per euro, the market convention. The source of the data is the EBS second-by-second ticker, which is provided to EBS’s clients to generate customer quotes and as input for algorithmic trading. These quotes are executable, not just indicative, and they therefore represent a true price series. We consider 5 full 24-hour trading days per week, each one beginning at 17:00 New York time;\(^7\) trading occurs around the clock on EBS on those days. We exclude all data collected from Friday 17:00 New York time to Sunday 17:00 New York time from our sample, as trading activity during weekend hours is minimal and is not encouraged by the foreign exchange trading community. We also drop several holidays and days of unusually light trading activity near these holidays in 2005: January 3, Good Friday and Easter Monday, Memorial Day, July 4, Labor Day, Thanksgiving and the following day, December 24–26, and December 30. Similar conventions on holidays have been used in

\(^7\)In the FX market, by global convention, the value date changes at 17:00 New York time (whether or not Daylight Saving time is in effect). This cutoff thus represents the threshold between two trading days.
other research on foreign exchange markets, such as by Andersen, Bollerslev, Diebold, and Vega (2003). The resulting number of business days is 251. In the analysis undertaken for this paper, we drop an additional 5 days in order to line up the FX trading days with those in the U.S. bond market, where some additional days are treated as holidays, as described below.

Table 1 presents some summary statistics for dollar/euro returns sampled at 24-hour and 5-minute intervals, where returns are calculated as log-differences of the dollar/euro exchange rate. The mean 24-hour return is about −5 basis points (−0.05 percent). The standard deviation of the daily returns in 2005 was about 56 basis points (0.56 percent). At the 5-minute frequency, the mean return is, of course, very near zero. In 2005, returns at the 5-minute frequency had a standard deviation of about 3 basis points, and they were extremely leptokurtic.

3.2 The bond data

We analyze high-frequency ten-year on-the-run Treasury cash market data from BrokerTec, also spanning January through December 2005. In the last few years, BrokerTec has become one of the two leading electronic brokers for inter-dealer trading in Treasury securities. Estimates of BrokerTec’s share of trading in on-the-run Treasury securities in 2005 range from 40 percent to 70 percent. BrokerTec operates an electronic limit order book in which traders can enter bid or offer limit orders (or both) and can also place market orders, similar to EBS. We refer our readers to Fleming (2007), Fleming and Rosenberg (2007), and Mizrach and Neely (2006) for discussions of several recent trends in the institutional aspects of trading in U.S. Treasuries. These authors also examine historical factors that underlie the current dominance of electronic trading systems for transacting in on-the-run U.S. Treasury securities.

The ten-year Treasury price data that we use are the mid-point of the highest bid and lowest ask quotes at the top of each second. As in the EBS data, the BrokerTec quotes are executable, not just indicative, and they therefore constitute a true price series. Unlike the EBS data, however, we focus on five 8-hour-long trading days per week, from 08:00 New York time to 16:00 New York time. BrokerTec operates (nearly) continuously on five days each week, from 19:00 New York time to 17:30 New York time, with Monday trading actually beginning on Sunday evening New York time. However, unlike trading in dollar/euro, the vast majority of trading in Treasury securities occurs during New York business hours (Fleming, 1997), and for this reason we limit our analysis to the 08:00 to 16:00 New York time frame. We excluded the same holidays and days of extremely light activity from our sample that we excluded from our EBS data. We also

---

8 The other leading electronic communication network (ECN) for trading in U.S. Treasuries is eSpeed.
9 Brokertec and EBS have both been acquired by ICAP in recent years. BrokerTec was acquired in 2003, EBS in 2006.
dropped a few additional days, which the U.S. Bond Market Association declared to be market holidays, from the sample.\footnote{There are also several days in the sample for which the Bond Market Association recommended a 14:00 closing time. We account for these days in our calculations of realized volatilities by limiting the day to 08:00 to 14:00 New York time and scaling the estimated volatilities appropriately.} The total number of business days retained for the bond data is 246.

Table 2 presents some summary statistics for bond returns sampled at 24-hour and 5-minute intervals, where the bond returns are calculated as log differences of the price of the ten-year on-the-run Treasury note. Daily returns are measured from 16:00 New York time readings. The mean daily price return is about -0.7 basis point (-0.007 percent), as the ten-year Treasury yield changed little on net in 2005. The standard deviation of daily bond returns was about 38 basis points in 2005.\footnote{As a rule of thumb, in the present case a 1-percent change in the price of the bond corresponds to about a 13 basis point change in the yield.} Returns at the five-minute frequency have a standard deviation of about 3 basis points, and they are also very leptokurtic.

### 3.3 Range of sample interval lengths and the prevalence of zero-return intervals

The highest available sampling frequency in our datasets is once every second, by construction. In order to have a reasonably large number of samples within each trading day at each frequency we consider, we set the longest sampling interval equal to 30 minutes (1,800 seconds) for the FX returns and to 15 minutes (900 seconds) for bond returns, resulting in within-day sample sizes of 48 and 32, respectively, at the lowest sampling frequencies.

A large fraction of the observed high-frequency returns in both markets under study is equal to zero. A zero return during a given sampling interval can occur either because the price changes during the sampling interval but then returns to its initial level before the interval ends or—much more commonly—because the price does not change at all. Table 3 presents the fraction of sampling intervals with zero returns in both markets, for sampling interval lengths ranging from 1 second to 10 minutes. At the 1-second sampling frequency, about 90 percent of all returns are zero in both series, although the fraction of zero returns is slightly higher for the bond data. At the 1-minute sampling frequency, 45 percent of all bond returns are zero and 26 percent of all exchange rate returns are zero.

Later in this paper, we consider in detail the consequences of the prevalence of sampling intervals with zero returns on the optimal selection of the sampling frequency and on the estimation of integrated volatility using absolute and bipower variation methods.
3.4 U.S. macroeconomic data releases

The impact of scheduled U.S. macroeconomic data releases on the level and volatility of foreign exchange and bond prices has been well documented (e.g., Andersen, Bollerslev, Diebold and Vega, 2003, for foreign exchange, and Fleming and Remolona, 1999, and Balduzzi, Elton, and Green, 2001, for Treasury securities). In parts of the empirical analysis below, we split the full sample into days with certain major U.S. macroeconomic announcements, selected because of their apparent impact on asset prices, and days without announcements. Our chosen monthly scheduled macroeconomic announcements are the employment report (non-farm payrolls and the rate of unemployment), the consumer price index, the producer price index, retail sales, and orders for durable goods. We also select the three quarterly GDP releases (advance, preliminary, final), each released quarterly, and the eight FOMC announcements in 2005. With the exception of the FOMC announcements, which are released at about 14:15 New York time, all announcements considered here are released at 8:30 New York time. Accounting for multiple announcements that occurred on some days in 2005, this gives us a subsample size of 62 days.\(^1\) We treat these days as announcement days irrespective of whether the actual data released differed from published market expectations or not.

4 Results for the standard estimator of integrated volatility

4.1 Overview

Figures 1A and 1B show the 2005 time series of daily estimates of the integrated volatility of FX returns and bond returns, based on the standard realized volatility estimator.\(^2\) Several conclusions may readily be drawn from these plots. First, for both series there is considerable dispersion in volatility across adjacent days. Second, in 2005 neither volatility series displays a discernible time trend or seasonality pattern, indicating that it may be meaningful to compute (suitably defined) averages in order to study general relationships between sampling frequency and realized volatility. Third, volatility is clearly higher, on average, on days with scheduled major U.S. macroeconomic news announcements, depicted by solid circles in both plots, than on non-announcement days, shown as open squares. This is particularly—but certainly not surprisingly—true for the bond return volatility estimates shown in Figure 1B.

A volatility signature plot, by common convention, graphs sampling frequencies on the horizontal axis and the associated estimates of realized volatility on the vertical axis. Such plots are used frequently in

\(^{12}\)Hence, the number of non-announcement days in the full sample is 184.

\(^{13}\)These realized volatilities are not computed for a single sampling interval of, say, 5 minutes. Instead, they are the averages of 9 separate volatility estimates, obtained from returns for sample lengths of 4 minutes, 4'15", 4'30", \ldots, 5'45", and 6 minutes. We elected to show these averaged realized volatility estimates because, as we demonstrate in greater detail later, on any given day these estimates can vary considerably even across closely-spaced sampling frequencies.
the empirical literature on realized volatility, as they provide an intuitive visual tool for the analysis of the relationships between these two variables. Quite often, it is possible to discern from a volatility signature plot a sampling frequency, which we label the critical sampling frequency, that serves to separate sufficiently-low frequencies (longer sample intervals), for which market microstructure noise does not seem to affect estimates of integrated volatility, from the higher frequencies (shorter sample intervals), for which market microstructure noise does appear to have an effect. We make extensive use of volatility signature plots in our paper. Because of the need to display a very wide range of sampling frequencies and because our focus is on the empirical effects of market microstructure noise—which are generally thought to be present in returns only at the higher sampling frequencies—we display the signature plots with a base-2 logarithmic scale on the horizontal axis, rather than with a standard, i.e., linear scale. The use of a logarithmic scale, by design, gives much more visual prominence to any changes in volatility for the shorter-length sampling intervals (higher sampling frequencies).

We note that the shapes of the daily volatility signature plots can vary considerably across days. Figures 2A, 2B, and 2C show signature plots for FX volatility for three days in 2005: October 3, an average volatility day; July 21, a day of very high volatility;\(^{14}\) and October 18, a day of slightly below-average volatility. It is immediately apparent that these signature plots differ not only in the ranges of their vertical scales but also in their shapes. On October 3 (Figure 2A), realized volatility decreases at first as the sampling interval lengths increase from 1 second to about 15 or 20 seconds, and then shows no further overall trend but a rapidly increasing dispersion as the lengths of the sampling intervals increase further all the way out to 30 minutes (1,800 seconds). On July 21, in contrast, the plot line at first declines slightly as the sampling interval length rises from 1 second to 3 seconds, but then increases on average (and also becomes much more dispersed) as the interval lengths increase further. Yet another pattern prevailed on October 18: the realized volatility at first decreases nearly monotonically as the sampling interval lengths rise from 1 second to about 20 seconds, then is roughly constant as the interval lengths increase to about 4 minutes (240 seconds), and declines once again as the interval lengths rise even more.

Considerable variation in the shape of the dependence of realized volatility on sampling frequency is also evident for bond returns for these three days. On October 3 (Figure 3A), the plot line at first decreases steadily up to a sample length of about 30 seconds, and then becomes quite dispersed for longer sampling intervals. Even though July 21 was not a day with a scheduled major macroeconomic news release, as defined in section 3.4, it was a day with far-above average volatility in bond markets as well, in part because of some spillover from the busy day in FX markets, but also because former Federal Reserve Chairman Greenspan

---

\(^{14}\)On July 21, 2005, after close of business in China but before the start of the business day in North America, the Chinese authorities revalued their currency, the renminbi, by 2.1 percent against the U.S. dollar. On that day, foreign exchange market volatility was quite elevated in most major currency pairs.
presented a part of the FOMC's semiannual monetary policy report that day. For this day (Figure 3B), realized volatility declines (almost) monotonically as the sample length increases. Finally, on October 18 (Figure 3C), the plot line at first declines sharply until returns are sampled every 30 seconds or so, and settles into a wide range of estimated volatilities for longer sampling intervals.

4.2 The dependence of realized volatility on the sampling frequency

As we noted in the discussion of Figure 1, the realized volatility of FX and bond returns is higher on average on days with scheduled major U.S. macroeconomic news announcements. This result is especially evident when one averages the volatility estimates over time, i.e., if the volatility signature curves are averaged separately for announcement days and non-announcement days.

Figure 4A shows the effect of averaging within each of these two types of days on the relationship between sampling frequency and realized volatility for dollar/euro returns. The plot highlights the stylized fact that if a day falls into the subset of announcement days, realized volatility is elevated relative to the subset of non-announcement days. In addition, the figure also shows that, on average, estimates of realized volatility on non-announcement days are quite insensitive to the choice of sampling interval length, at least as long as it falls into a range from about 20 seconds to about 10 minutes. In contrast, for sampling intervals shorter than 20 seconds, the estimates of integrated volatility are noticeably higher, and they increase progressively as the interval lengths decrease. This suggests that whereas market microstructure noise is present and affects realized volatility at the very highest sampling frequencies, it does not have a noticeable effect on realized volatility for sampling frequencies lower than once every 20 seconds. This same general finding also applies for the subset of days with major scheduled economic announcements: realized volatility increases markedly if returns are sampled more often than once every 15 seconds.\footnote{We also observe that, in contrast to the case of non-announcement days, where the plot line is virtually flat for frequencies lower than the critical frequency, the plot line declines steadily (though only slightly) as the sampling interval length increases beyond 15 seconds. This suggests that FX trading dynamics on announcement days in 2005 may also have been characterized by a small amount of mean reversion at medium frequencies rather than just at the highest frequencies (as would be the case if the dynamics were purely of the microstructure variety).} Note that for the case of FX returns, the critical sampling frequencies, i.e., the frequencies above which market microstructure noise has an increasingly important impact on realized volatility, are roughly the same in the two subsamples.

Figure 4B shows the time-averaged signature plots of bond returns for announcement days and for non-announcement days. One notes immediately that, for any given sampling frequency, integrated volatility is much higher on announcement days than it is on non-announcement days. In addition, it appears that, on average, the contribution of market microstructure noise to realized volatility is considerably larger for bond returns, as the slopes of the (time-averaged) signature plots are steeper at the very highest sampling frequencies than was the case for FX returns. Third, and of the most relevance for the purposes of our
paper, the critical sampling frequency is rather different from the FX case, for both announcement and non-announcement days. It is in the range of once every 120 to 180 seconds on days without scheduled major macroeconomic announcements, and about once every 40 seconds on announcement days. We infer that even though volatility is higher on announcements days, the critical sampling frequency is at least three times higher on announcement days than on non-announcement days. This finding clearly suggests that it is preferable to sample bond returns more frequently on announcement days than on non-announcement days, in order to obtain volatility estimates that are more precise yet not affected noticeably by market microstructure noise.

To sum up, when using the standard realized volatility estimator, the signature plots suggest that it is possible to sample FX returns as frequently as once every 20 seconds on non-announcement days (15 seconds on announcement days), and to sample bond returns as often as once every 2 to 3 minutes on non-announcement days (once every 40 seconds on announcement days), without incurring a significant penalty in the form of an upward bias to estimated volatility. Our findings regarding the critical sampling frequency for volatility estimation for FX returns are quite different from those reported by other researchers, who have typically focused on returns to individual equities and have suggested that one should not sample more often than once every 5 minutes or so if one wishes to avoid bias caused by market microstructure dynamics (e.g., Andersen, Bollerslev, Diebold, and Ebens, 2001).

We have already noted that there is considerable variability in the shapes of the daily volatility signature plots, and that some of this variability appears to be associated with the arrival of macroeconomic news. To illustrate that there is considerable variability in the shapes of the signature plots even within the subset of just the non-announcement days, we show the median, the first and third quartiles, and the 5th and 95th percentiles of the distribution of realized volatility estimates, computed from non-announcement days only. To simplify the exposition, we show these quantiles (see Figure 5A for FX and 5B for bonds) standardized by the average of each day’s volatility estimates for 9 sampling frequencies in the 4 minute to 6 minute range. For FX returns (Figure 5A), one can again note the wide array of sampling interval lengths, from about 20 seconds to about 10 minutes, for which the median standardized volatility estimate is remarkably insensitive to the choice of sampling frequency. The interquartile range and the 90-percent confidence band become increasingly wider as the sampling frequency moves away from the 4 to 6 minute range. But even at sampling frequencies in the 4 to 6 minute range, one notes that the widths of both the interquartile range and the 90-percent confidence band are not close to zero. This shows that estimates of realized volatility can be quite sensitive to the precise choice of sampling frequency even when these sampling frequencies are very close to each other.
The analogous graph for bond returns, Figure 5B, is qualitatively similar to Figure 5A, but it differs from the FX case in two important ways (in addition to the already-noted narrower range of frequencies, over which the median normalized volatility estimate is close to 1). First, at the 1-second frequency, the median volatility estimate is more than three times larger than the 4-to-6 minute average median estimate. Second, the confidence intervals widen out even more quickly as the sampling intervals move away from the 4-to-6 minute range. Thus, bond return volatility estimates are not only affected more strongly by market microstructure effects than FX returns are, but their heterogeneity is also far larger. We discuss some of the consequences of these observations for applied work in Section 7.

4.3 A formal rule for choosing the optimal sampling frequency

In addition to examining volatility signature plots, one may wish to have a more formal method for establishing the critical sampling frequency. One such method is the optimal sampling rule of Bandi and Russell (2006b), which was introduced in Section 2 and is also very similar to the rule developed by Aït-Sahalia et al. (2005). The optimal sampling frequencies for each day of the sample, based on equation (9), are shown in Figures 6A and 6B. The average sample interval lengths across all days in the full sample are 170 and 310 seconds, respectively, for FX returns and bond returns. Although there is a fair degree of variation from day to day, these averages are nevertheless considerably above those we deduced from the volatility signature plots shown in the previous section. This is especially true for the FX returns.

Signature plots are, of course, informal graphical tools which cannot by themselves deliver unambiguous answers. Nevertheless, signature plots are essentially model-free and they rely on much less stringent assumptions about the nature of the data generating process than the formal sampling rule. For example, Bandi and Russell (2006b) assume that there are no jumps in the price process. Moreover, it is also possible that the variance of the noise term cannot be estimated sufficiently accurately from the returns sampled at the second-by-second frequency, which is the highest-available frequency in both datasets. Recall that, according to the signature plots, it may be possible to sample as often as once every 15 to 20 seconds in the FX market without incurring a significant bias caused by market microstructure features. It may well be the case that returns sampled at the one-second frequency still contain too much signal—and hence not enough noise—in order to be able to estimate consistently; Hansen and Lunde (2006) make a similar point. This issue may be less of a problem for the bond returns, where the signature plots had indicated critical sampling intervals in the 2 to 3 minute range. This may explain why the results from the signature plots and the Bandi-Russell sampling rule are somewhat closer to each other for bond returns than they are for FX returns.
It is interesting to note that the optimal sampling frequencies obtained using the Bandi and Russell rule are higher, i.e., the implied sampling interval lengths are shorter, on days with scheduled major macro announcements. This confirms one of the findings we obtained from the signature plots, which is that even though market microstructure noise is likely to be greater on announcement days (for instance, in terms of a larger bid-ask spread), the signal is even stronger on such days, implying that returns can be sampled more frequently on announcement days.

As was noted in Section 3.3, when returns are sampled at very high frequencies, many of the FX and bond returns are zero because there is no price change over many of the short time intervals. Phillips and Yu (2006a and 2006b) note that the prevalence of flat pricing over short time intervals implies that the market microstructure noise and the unobserved efficient price components of the observed price process are negatively correlated over these periods, and that these two components may become perfectly negatively correlated as $\delta \downarrow 0$. Put differently, the maintained assumption that the market microstructure noise is independent of the latent price process, which underlies the derivation of the Bandi and Russell rule, cannot be strictly valid if the observed price process is discrete rather than continuous. In such a framework, sampling at ever-higher frequencies ultimately does not even produce a consistent estimator of the variance of the market microstructure noise. If this feature of the data is not taken into account, the Bandi and Russell rule will tend to lead to choices of the optimal sampling interval lengths that are too large. We interpret our empirical results as being fully consistent with this theoretical observation.

5 Kernel-based methods

5.1 Autocorrelations in high-frequency returns

The use of the realized kernel estimator of integrated volatility, described in Section 2.4 above, is motivated along lines similar to those for heteroskedasticity and autocorrelation consistent (HAC) estimators of the long-run variance of a time series in traditional econometrics (e.g., Newey and West, 1987). That is, by adding autocovariance terms, an estimator is constructed which better captures the relevant “long-run” variance in the data. Before showing our empirical results for the performance of the BHNLS realized kernel estimator, it is therefore instructive to study the autocorrelation patterns in the high-frequency intraday returns data to build up some intuition that will help guide the interpretation of our empirical results.

Figure 7A shows the average autocorrelation across all days in the FX returns, out to 30 lags, for data sampled at the 1, 10, 30, and 60-second sampling frequencies. That is, for a given lag and sampling frequency, the within-day autocorrelation in high-frequency returns is calculated for each day and is then averaged.
across all days in the sample. The corresponding results for the bond returns are shown in Figure 7B. When sampling at the 1-second frequency, it is evident that there is some negative autocorrelation in the returns, and that this correlation stretches out for about 10 to 15 lags, i.e., that non-zero serial dependence in 1-second returns persists for about 10 to 15 seconds. For returns sampled at the 10-second frequency, there is still some evidence of negative autocorrelation at the first 2 lags in the FX returns and in the first 4 to 5 lags in the bond returns. For returns sampled at the 30- and 60-second frequencies, there is little evidence of any systematic pattern in the autocorrelations of the FX returns; for the bond returns, only the first two serial correlation coefficients are nonzero for these two sampling frequencies.

The autocorrelation patterns shown in Figure 7 correspond well to the findings using signature plots of how often one can sample returns when using the standard realized volatility estimator. In particular, there is little evidence of any autocorrelation in the FX data for returns sampled at frequencies lower than once every ten seconds. The conclusion from the volatility signature plots shown above was that the critical sampling frequency for FX returns is in the 15 to 20 second range. This finding corresponds very well to the fact that FX return autocorrelations are insignificant for time spans beyond about 20 seconds. Similarly, because there is still a large amount of negative first-order autocorrelation in the one-minute bond returns, it is not surprising that we also obtained a much lower critical sampling frequency for this asset using the signature plot method.

Overall, the results in Figure 7 suggest that in the case of FX returns and for sampling interval lengths shorter than 30 seconds, using kernel estimators should help reduce any bias in realized volatility estimates. For the bond returns, the same would seem to hold for returns sampled at frequencies higher than once every 2 minutes.

5.2 Optimal bandwidth choice

The graphs in Figure 7 give some indication of how many lags one may want to include in the realized kernel estimator in equation (11). However, they do not, by themselves, provide a simple prescription for action. BNHLS also propose a rule for an optimal choice of the bandwidth or lag truncation parameter. They show that, in their framework, the optimal bandwidth is a function of both the sampling frequency and a scale parameter, $\hat{c}$, which is independent of the sampling frequency; $\hat{c}$ must be estimated, and the details are given in BNHLS. The optimal bandwidth is then given by $H = \hat{c} n^{1/2}$, although for very high sampling frequencies (and hence for very large values of $n$) BNHLS recommend setting $H = \hat{c} n^{2/3}$. We use this latter formula for sampling intervals shorter than 30 seconds.
The time series of optimal bandwidths in 2005 for returns sampled at the 1-second frequency are shown in Figure 8. For FX data (Figure 8A), the optimal bandwidths range between 4 and 7, and for bond returns (Figure 8B), the optimal bandwidths are typically between 6 and 10. There seems to be little systematic variation between announcement and non-announcement days. The optimal bandwidths are roughly similar to, but usually somewhat smaller, than the number of lags for which there seems to be a non-zero autocorrelation in the 1-second returns (Figure 7). As with any kernel estimator, the choice of the value for the bandwidth parameter involves a bias-variance trade-off, with a larger value leading to a smaller bias but also a higher variance. The optimal bandwidth choice incorporates this bias-variance trade-off. It is, in general, not optimal to control for all of the autocorrelation in the data by using a very large value for the bandwidth parameter, as doing so may induce a lot of variance into the estimator.

Calculating the optimal bandwidth parameter $H$ for returns sampled at the 1-minute and lower frequencies, we find that the result is always a number between 0 and 1, for both financial asset returns series and for all days in the sample. Depending on whether one rounds the results up or down—recall that the bandwidth has to be an integer—the result is thus always an optimal bandwidth of either 0 or 1 for these lower sampling frequencies. In fact, all of the optimal bandwidths are less than 0.5, so that simple rounding would yield 0 as the optimal number of lags in equation (11) for sampling frequencies equal to or less than once a minute. Throughout the rest of the analysis reported in this section, the estimate for the optimal bandwidth is always rounded up, so that at least one lag is always included in the realized kernel estimator that incorporates the optimally chosen bandwidth for each sampling frequency.

In summary, for the very highest sampling frequencies available in our dataset, the bandwidth selection rules of BNHLS suggest that a moderate number of lags should be included, but for lower sampling frequencies the rule indicates that at most one lag should be included.

### 5.3 Signature plots for realized kernel estimates

In this section we display signature plots for 6 different choices of $H$: the standard realized volatility estimator (which corresponds to the realized kernel estimator with bandwidth zero), the realized kernel estimator with fixed bandwidths of 1, 5, 10, and 30, and the realized kernel estimator that uses a bandwidth optimally chosen for each sampling frequency.

As we did in Section 4 for the standard realized volatility estimator, we begin by studying the volatility signature plots for three specific business days in 2005. Signature plots for FX returns on these days are displayed in Figure 9, while signature plots for bond returns are shown in Figure 10. Figure 9A shows the signature plot of FX returns on October 4, 2005, which was a day of average volatility. For this day, we easily
observe the pattern that one would expect as a result of changing the bandwidth parameter. The standard estimator, which is obtained by setting $H = 0$, yields nearly constant estimates of realized volatility (of about 8.5 percent at an annualized rate) for all sampling interval lengths between about 15 seconds and about 4 minutes; in contrast, for sampling frequencies higher than about once every 15 seconds the standard estimator is biased upwards, and it becomes increasingly more biased as the sampling frequency increases. For bandwidths greater than 0, the influence of market microstructure noise on realized volatility becomes increasingly less pronounced, especially at the highest-available sampling frequencies. For $H = 1$ (the blue short-dashed line), we find that one can sample as frequently as once every 5 seconds without incurring any apparent bias in estimated volatility; setting $H = 10$ would allow us to sample as frequently as once every 2 seconds; and if one were to use 30 lags in the kernel estimator, there is no apparent bias even at the 1-second sampling frequency. Using the optimal bandwidth produces a signature plot that is quite similar to the one that results from using a fixed bandwidth equal to 1.

Our findings regarding the effects of varying $H$ on realized kernel estimates of volatility are very similar for October 18, 2005, which was a low-volatility day; see Figure 9C. In contrast, for the high-volatility day of July 21, 2005, shown in Figure 9B, it is harder to draw any firm conclusions. On that day, using a value of $H > 1$ would result in estimates of realized volatility that are actually slightly larger than those obtained with the standard estimator, except when the sampling interval lengths are as short as 1 or 2 seconds. It is worth noting that volatility and trading volume were both exceptionally high on that day, and hence it may not even be necessary to employ a kernel-based correction for this specific day in order to obtain a low-bias estimate of volatility.

The results for the bond returns on the same three dates are overall quite similar to those for FX returns, but there are also some striking differences. In Figure 10A, for the medium-volatility day of October 5, 2005, we see a pattern that is fairly similar to the one we observed in Figure 9A for FX returns: setting $H = 1$ already achieves important gains in terms of the usable critical sampling frequency, from about once every 20 seconds to once every 4 seconds; by $H = 10$, one can sample as frequently as once every second; and increasing the bandwidth further to $H = 30$ produces little additional gain for any of the higher sampling frequencies of interest.\textsuperscript{16} For July 21, 2005, setting $H = 1$ shortens the critical sampling interval length from about 2 minutes to about 30 seconds, and setting $H = 10$ or $H = 30$ reduces the length of this interval further, to about 15 seconds. The patterns for the low-volatility day of October 18, 2005, shown in Figure 10C, also suggest that setting $H = 1$ or $H = 5$ achieves significant gains in terms of the achievable critical sampling frequency, raising it to about once every 4 to 8 seconds.

\textsuperscript{16}For the bond returns, kernel estimates with $H = 30$ are not reported for the lowest sampling frequencies, i.e. the longest sampling intervals, since there are not enough observations available at these frequencies to form an estimate when using 30 lags.
Figure 11 shows the signature plots of FX returns averaged separately for non-announcement days and announcement days in 2005. As was discussed in Section 4, when using the standard realized volatility estimator the critical sampling interval length for FX returns on non-announcement days and announcement days, respectively, was between 15 and 20 seconds in 2005. By including just one lag in the realized kernel estimator, the critical sampling interval length for FX returns drops to about 4 seconds (on average) on non-announcement days. Using the optimal bandwidth selection rule of BHNLS results in a similar critical sampling interval length. If one sets $H = 10$ or $H = 30$, even sampling at the 1-second frequency seems admissible for the purpose of calculating realized volatility. On the subset of announcement days, shown in the lower panel of Figure 11, setting $H = 1$ shortens the critical sampling interval length to about 8 seconds, and setting $H = 5$ shortens this interval still further, to about 4 seconds. The results for the bond returns, shown in Figure 12, are similar in nature to those for FX returns. Whereas the critical sampling frequency for the standard estimator of realized volatility on non-announcement days is between once every 2 to 3 minutes, including just 1 lag in the realized kernel estimator increases the critical sampling frequency to about once every 40 seconds on non-announcement days and once every 30 seconds on announcement days; using 30 lags, this frequency climbs to about once every 8 seconds, on both types of days in 2005.

5.4 Implications for practical use of realized kernel estimators

The results just presented indicate that there is considerable scope for achieving much higher critical sampling frequencies, for FX and bond returns, by using a kernel estimator rather than the standard estimator of realized volatility, and thereby also achieving greater precision in the estimates of volatility. There is, however, a bias-variance trade for the number of lags included in the realized kernel estimator. Thus, even though we find that using 30 lags would allow us to sample at the 1-second frequency in the case of FX returns and the 8-second frequency for bond returns, it may not be optimal to do so. Indeed, according to the BHNLS rule, the (time-averaged) optimal bandwidth at the 1-second frequency is always much smaller than 30. Using the optimal bandwidth, the critical sampling frequency appears to be about once every 2 to 5 seconds for FX returns, while for bond returns it is about once every 30 to 40 seconds. Unfortunately, calculating the optimal bandwidth is fairly complicated. However, judging by the results shown in Figures 9, 10, 11, and 12, our empirical results for the kernel-based realized volatility estimator using the optimally chosen bandwidth are very similar for those we found using the kernel estimator with a fixed lag length of 1. Note that for $H = 1$ the kernel estimator has a very simple functional form, viz.

$$\bar{K}_t (X_{\delta}) = \gamma_0 (X_{\delta}) + 2\gamma_1 (X_{\delta}) ,$$  \hspace{1cm} (17)
because if $H = 1$ we have $k(0) = 1$ in equation (11). Therefore, at least for the two financial returns series studied in this paper, we find that by augmenting the standard realized volatility estimator with just one additional term, the critical sampling frequency can be increased considerably without giving up much in terms of the simplicity of the calculations. This estimator is, incidentally, also identical to the noise-corrected estimator proposed in the seminal paper of Zhou (1996).

6 Estimation of integrated volatility using absolute power and bipower variation methods

The standard estimator of integrated volatility is potentially quite sensitive to outliers, as it is computed from squared returns. This raises the issue of how robust estimators of volatility, which are functions of absolute rather than squared returns, perform in practice. As discussed before, these estimators converge to measures of the daily variation of the diffusive, or non-jump, part of the returns process. Since much of the difference in daily volatility that was seen for announcement days relative to non-announcement days (Figure 4), may very well stem from jumps rather than diffusive moves in returns, it is particularly interesting to examine how estimates of volatility differ between announcement and non-announcement days when the two robust methods are used. In addition, we also study the degree to which market microstructure noise affects estimates of volatility across sampling frequencies when robust estimators are employed.

6.1 Volatility estimation using absolute variation methods

The realized absolute variation of a continuous time diffusion process $X$, sampled over $[0, t]$ at intervals $\delta$, was introduced earlier as

$$RAV_t = \mu_1^{-1} n^{-1/2} \sum_{j=1}^{n} |X_{\delta j} - X_{\delta(j-1)}|.$$  \hspace{1cm} (18)

The factor $\mu_1^{-1}$ is needed to obtain an estimate of the mean absolute variation of $X_t$ over $[0, t]$, $\int_0^{t} \sigma_u du$, under the diffusion model (2), rather than of the average absolute return of $X_t$ over that period.\footnote{For a Brownian diffusion, $\mu_1^{-1} = \sqrt{\pi/2} \approx 1.253$. For dollar/euro returns from January 1999 to September 2006, the ratio of the standard deviation of daily returns to the mean absolute daily return was equal to 1.31, with yearly estimates of this ratio falling in the interval $[1.27, 1.33]$. For 2005, this ratio was 1.29, and it is this value, rather than $\mu_1^{-1}$, that we use in the empirical work on the volatility of FX returns in this section; for daily-frequency returns on the 10-year Treasury note, the corresponding ratio was 1.26 in 2005.} Because

The returns of many financial time series are generally much more heavy-tailed than draws from a normal distribution are, especially when the returns are sampled at very high frequencies. For the case of the Student-$t$ distribution (a well-known class of heavy-tailed distributions), the ratio of the distribution’s standard deviation to its absolute first moment is a function of $\nu$, the degrees of freedom parameter. For values of $\nu$ equal to 3, 5, and 10, this ratio is close to 1.57, 1.36, and 1.29, respectively. In principle, this dependence of the conversion factor on the distribution’s tail shape parameter, and the fact that the leptokurtosis of returns increases with the sampling frequency, both indicate that one should use a conversion factor that varies systematically with the sampling frequency. A full treatment of this issue is left to future research.
a diffusion process has unbounded absolute variation, scaling by $n^{-1/2}$ is required to obtain an estimator that converges to a proper limit as the sample size, $n$, increases to infinity. Because real data are generated discretely and not continuously, the term \textit{sample size} needs to be interpreted carefully in empirical work. When data are generated discretely, there will be time intervals during which no new data arrive and hence returns are zero. Furthermore, the relative frequency of zero-return intervals increases as sampling frequency rises.\textsuperscript{18} With discretely-generated data, then, one must take care not to use the theoretical sample size, $[t/\delta]$, that corresponds to a given sampling interval length $\delta$, as more and more of the sample periods will be characterized by zero returns as $\delta \downarrow 0$. Instead, one must use the effective sample size, i.e., the number of intervals within a day during which a transaction occurred.

We compute estimates of the daily variation based on the realized absolute variation of FX and bond returns using the same range of sampling frequencies as in the preceding section, and we also average separately across announcement and non-announcement days. The resulting signature plots are shown in Figures 13A and 13B. These plots share certain similarities with the ones shown in Figures 4A and 4B, but they also exhibit some important differences. First, we find that the estimates of daily variation that are based on absolute returns differ by less, on average, across announcement and non-announcement days than is the case for the volatility estimates that are based on squared returns. This suggests that the jump components of returns, which presumably are both more frequent and more pronounced on announcements days, indeed disproportionately affect the standard realized volatility estimator, as the asymptotic theory for this estimator would predict. This effect is particularly strong for FX returns (Figure 13A): volatility estimates show little difference across the two subsamples when they are computed using absolute returns.

A second important difference between the signature plots for the robust estimators in Figures 13A and 13B and those for the standard realized volatility estimator in Figures 4A and 4B lies in their response to the variations in the sampling frequency. For both FX and bond returns, and both on announcement days and on non-announcement days, realized volatility increases faster with the sampling frequency if it is computed as a functions of absolute returns than as a function of squared returns. While we can not offer a detailed explanation for this finding, we conjecture that this difference may offer important clues to the nature of the market microstructure noise process that affects returns at the very highest frequencies.

Judging from the absolute variation signature plots, the critical sampling frequency, which separates those estimates which are affected noticeably by market microstructure noise from those which are not, is about 4 to 5 minutes for both FX and bond returns, and for both announcement and non-announcement days.

\textsuperscript{18}For a 24-hour (8-hour) trading day and a 1-second sampling frequency, the theoretical sample size is 86,400 (28,800). As is shown in Table 3, on an average trading day in 2005 the effective sample size for FX and bond returns at this frequency was only 13.9 percent and 7.6 percent, respectively, as large as the theoretical sample size. We note that these numbers represent averages across all trading days within the year. The fraction of 1-second intervals with non-zero returns within a day can vary considerably across days.
These estimates of the critical sampling frequencies are substantially lower, and the associated sampling interval lengths are therefore substantially longer, than those we found when computing realized volatility using squared returns. Exploring the causes of this pronounced difference is also left to future research.

6.2 Integrated volatility estimated from bipower variation

We now turn to volatility signature plots obtained from the bipower variation of processes. As discussed in Section 2, bipower variation is calculated from the products of adjacent absolute returns, rather than simple squared returns, and it is therefore more robust to large outliers such as non-diffusive jumps. Figures 14A and 14B show the signature plots for FX and bond returns using the realized bipower variation estimator defined in equation (13).

The patterns shown in the bipower signature plots are strikingly different from those shown in the signature plots that are based on squared or absolute returns, as the bipower-based signature plots exhibit what appears to be a downward bias to estimated volatility at higher sampling frequencies. Although we cannot rule out that market microstructure noise could account for a part of this difference, the most likely determinant of this feature is the fact that, as the sampling frequency increases, the fraction of sampling intervals with zero returns increases as well. Because the bipower variation estimator is calculated from the sum of the products of adjacent absolute returns, 2 consecutive non-zero returns are required to obtain a non-zero increment to the estimate of volatility. Because the prevalence of such consecutive pairs of non-zero returns declines sharply as the sampling frequency increases, the result is a decline in estimated volatility.

The critical frequency, at which the signature plots indicate that it is safe to sample without incurring a penalty from market microstructure noise, thus reflects both the actual properties of the microstructure noise process as well as the relative scarcity of non-zero observations at various sampling frequencies. For the bipower-based volatility of FX returns, this frequency appears to be around 15 to 30 seconds on announcement days and around one minute on non-announcement days. For bond returns, the critical frequencies are around one and two minutes, respectively, on announcement and non-announcement days.

Figures 15A and 15B show the signature plots for the realized bipower variation using the skip-one returns defined in equation (16). Rather than computing products of adjacent absolute returns, this estimator relies on products of absolute returns with one sample period left out in between the terms. The intuition for this

\[ \sqrt{RBV} \]

The volatility, rather than variance, estimates are shown, i.e., results for \( \sqrt{RBV} \) are displayed.

This downward bias at higher sampling frequencies is especially prominent for the case of FX returns. It is somewhat less pronounced for the case bond returns, except at the very highest sampling frequencies.

Note that in the case of the absolute power variation method, a natural way for adjusting the estimator for changes in the prevalence of intervals with zero returns is to adjust the sample size, i.e., to set the sample size equal to the number of intervals with non-zero returns. No such simple adjustment is available for the estimator that is based on the bipower variation of returns. We conjecture that, when computing the bipower variation of a discretely-generated process, a practical method for dealing with the incidence of intervals with zero returns is to discard all samples that have zero returns prior to calculating the bipower products.
method is that, by “skipping over” one term, one may be able to eliminate some of the serial correlation in returns that could be caused by market microstructure features. Unfortunately, the actual volatility estimates we obtain using the skip-one method are not straightforward to interpret. Across most sampling frequencies and for both FX and bond returns, estimated volatility using the skip-one bipower method tends to be lower than if it is computed on the basis of the standard bipower estimator. This result could be due to a successful elimination of market microstructure noise. However, we find that this result is also present at longer sampling interval lengths, for which microstructure noise is thought to play a less significant role. Hence, the lower levels of the volatility estimates using the skip-one method almost certainly also reflect patterns in the latent efficient-price component of the observed returns process. For instance, if large absolute returns tend to cluster in practice, the skip-one estimator is likely to be biased downward irrespective of the chosen sampling frequency.

In summary, we find that it is hard to assess the impact of market microstructure noise on volatility estimated from the realized bipower variation of a process. The primary cause of this difficulty appears to be the issue of zero returns in samples that are drawn from discretely generated data. Nevertheless, it is evident that the choice of sampling frequency is important for this class of volatility estimators as well. There is some evidence that using the skip-one estimator may help eliminate some of the noise, as suggested by the fairly flat signature plots for bond returns in Figure 15B, but this estimator may also induce a downward bias that depends on the conditional distribution of the efficient-price component of the returns process. Given the increasing popularity of the bipower volatility estimator, an important topic for future research is the development of formal rules for choosing the critical or optimal sampling frequency. In addition, it would appear to be useful to develop kernel-based or subsampling-based extensions to volatility estimators that are based on the absolute power variation and bipower variation of the returns process.

7 Discussion

Using volatility signature plots, we have found that the critical or optimal sampling frequency, which affords estimation of integrated volatility without incurring a penalty in the form of an upward bias caused by market microstructure noise, is considerably higher and the resulting intraday sample lengths are considerably lower, by a factor of at least six, for FX returns than for bond returns. What are some of the—not necessarily independent—factors that may explain this striking difference? Both markets are based on electronic order book systems, and both have achieved large market shares in their respective fields. However, the number of active trading terminals is considerably larger on EBS than on BrokerTec, as is the number of transactions per day. In contrast, the average size of each transaction is lower on EBS than it is on BrokerTec, suggesting
that the price impact of EBS transactions may also be lower on average. In addition, the bid-ask spread in the dollar/euro exchange rate pair is, on average, only about sixty percent the size of that of the 10-year Treasury note. All of these factors may explain the observed differences in the critical sampling frequencies.\footnote{It is also possible that the workup process on BrokerTec affects bond price dynamics in a way that makes market microstructure noise persist longer than in FX markets. BrokerTec has recently changed the mechanics of its workup process significantly.}

Judging from the volatility signature plots, the critical sampling frequencies for estimating the realized volatility of the returns to the 10-year Treasury securities and, even more so, of the returns to the dollar/euro pair are much higher, and the associated critical sampling interval lengths are therefore shorter, than those reported in the empirical literature for all but the most liquid of exchange-traded shares (e.g., Bandi and Russell, 2006b). Lower bid-ask spreads and other lower transaction costs, a smaller price impact of trades, and the fact that the number of distinct assets traded on these two systems is quite small—which, ceteris paribus, should raise their liquidity—are all good candidates for explaining why their critical sampling frequencies are so much higher than those in some other financial markets.

Two additional findings reported in this paper are that there is, in general, substantial heterogeneity in the shapes of the daily volatility signature plots and that, on any given day, the realized volatilities computed from adjacent sampling frequencies can differ considerably from each other. A related finding, we believe, is that the sampling interval lengths chosen by the rules proposed by Bandi and Russell (2006b) and Aït-Sahalia et al. (2005) are generally considerably longer than those that would be chosen visually, i.e., on the basis of the signature plots. We conjecture that a key to interpreting these findings is to recall that financial returns—and especially those sampled at very high frequencies—tend to be very leptokurtic. Empirically, returns that occur during possibly just a handful of intraday periods may make disproportionate contributions to estimates of realized volatility, and these contributions can depend strongly on the precise choice of sampling frequency. The heterogeneity in the shapes of the daily signature volatility plots may also be a byproduct of the high kurtosis present in high-frequency data. We suggest that one of the practical uses of computing realized volatility via robust methods—such as those that are based on the absolute power, bipower, and multipower variation of returns—may be to shed more light on the role leptokurtosis of returns plays in driving the heterogeneity present in daily (squared) realized volatility signature plots.

Volatility is higher, for both of our returns series, on days with scheduled major macroeconomic data releases and news announcements. This finding is fully consistent with virtually all of the existing literature on this subject; see, e.g., Fleming and Remolona (1999) for a review of the impact of economic news in the U.S. Treasury market. The method we use to capture the impact of macro and news events on volatility—partitioning the full sample into two subsets, based on whether a day has a scheduled major news announcement or not—is admittedly simplistic, and it is not meant to represent a full accounting of the
ways that news and data affect financial market returns and their volatility. For instance, there are many
days with scheduled economic news announcements—such as Chairman Greenspan’s delivery of the FOMC’s
semiannual monetary policy report on July 21, 2005—that are not captured explicitly in the econometric
work performed for this paper. In addition, there are also many unscheduled announcements—such as
the decision by Chinese government officials to revalue their currency against the dollar on July 21, 2005.
Obviously, unscheduled announcements may be every bit as important for returns and volatility as scheduled
announcements are. Clearly, an examination of the actual historical news arrival record, of the news content
(or surprise component) of scheduled announcements and data releases, and of the relative importance of
various data releases and news announcements (and any shifts over time of their relative importance), is
essential for developing a fuller understanding of the relationships between news and realized volatility.

8 Conclusion

In this paper, we use various methods to examine the dependence of estimates of realized volatility on
the sampling frequency and to determine if the data suggest that there exist critical sampling frequencies,
beyond which estimates of integrated volatility become increasingly contaminated by market microstructure
noise. We study returns on the dollar/euro exchange rate pair and on the on-the-run 10-year U.S. Treasury
security in 2005, at intraday sampling frequencies as high as once every second. We detect strong evidence
of an upward bias in estimated volatility at the very highest sampling frequencies. Time-averaged volatility
signature plots suggest that FX returns may be sampled as frequently as once every 15 to 20 seconds,
respectively, on days with and without scheduled major U.S. economic data releases and news announcements,
without the standard realized volatility estimator incurring market microstructure-induced bias. In contrast,
returns on the 10-year Treasury security should be sampled no more frequently than once every 2 to 3 minutes
on non-announcement days, and about once every 40 seconds on announcement days, if one wishes to avoid
obtaining upwardly-biased estimates of realized volatility.

If one uses realized kernel estimators, which explicitly eliminate some of the serial correlation in the returns
that is induced by market microstructure noise, the critical sampling frequencies increase even further. By
using the simplest possible realized kernel estimator, which simply adds the first-order autocovariance term
to the standard estimator, the critical sampling frequency for FX returns is about once every 2 to 5 seconds,
and it is about once every 30 to 40 seconds for bond returns.
